Figure 1 *Blastomyces dermatitidis* grows as a mold at 30°C or below (a) and as thick-walled yeast cells that divide by budding on a broad base (b) in infected mammalian tissues or at 37°C . Images courtesy of Bruce Klein, University of Wisconsin.

Epidemiology

Most cases of blastomycosis occur in the Central and Eastern United States. Areas of highest prevalence include the lower Mississippi River Valley, the Ohio River Valley, the Carolinas, and regions including the Great Lakes and the St. Lawrence River Valley. There are also microfoci in Central and South America and parts of Africa. Conidia are thought to be the infectious forms of *B. dermatitidis*.

Analysis of sporadic cases indicated that persons at greatest risk in endemic areas include farmers, hunters, forestry workers, and campers. More males than females have historically been diagnosed with blastomycosis, but analysis of several distinct outbreaks has not established any gender or racial differences in susceptibility. Blastomycosis is also common in dogs and other mammals.

Pathogenesis and clinical features

Infectious particles (presumably conidia) are inhaled into the lungs of humans or animals, where they convert into the pathogenic yeast forms. Infection in the lungs elicits an inflammatory reaction with features of both acute inflammation and granuloma formation. Most infections resolve spontaneously and are thus asymptomatic and cause minimal symptoms, but some infections progress to cause progressive pulmonary infection and/or disseminated extrapulmonary disease. Several virulence-associated properties and genes have been studied. One example is a protein on the surface of *B. dermatitidis* (WI-1) that mediates adhesion to host cells.

The ability of an infected host to mount an acute inflammatory reaction and to acquire specific cell-mediated immunity is important for defense against *B. dermatitidis*. Although severe blastomycosis can occur in patients with abnormal immune defenses, *B. dermatitidis* is associated with infection of compromised hosts less often than are most other pathogenic fungi.

Because most pulmonary *Blastomyces* infections are asymptomatic or associated with only mild symptoms, blastomycosis is usually not recognized unless there is persistent or progressive pneumonia or a dissemination to extrapulmonary sites. Symptoms of pulmonary blastomycosis include fever, chills, productive cough, and chest pain. Individuals who do not recover from the early manifestations of infection develop a progressive granulomatous and suppurative pulmonary infection, or the infection may disseminate to other organs. The most common sites of dissemination are the skin and bones, although other tissues can also be involved. The typical skin lesion is a chronic progressive ulcer that is often misdiagnosed as neoplasia.

Diagnosis and treatment

The diagnosis of blastomycosis is based on demonstrating the causative organism in infected tissues or body fluids (e.g., sputum and bronchial washings, other body fluids, skin scrapings, and tissue biopsies), either by microscopy or by culture. The finding of thick-walled, broad-based, unipolar budding yeast-like cells, 8–15 μm in diameter in the collected material or within tissue, is highly suggestive of blastomycosis, and the diagnosis is proven by isolating *B. dermatitidis* in culture. Because the fungi isolated in culture are often molds without distinctive morphologic features, definitive identification of these fungi as *B. dermatitidis* can be accomplished with commercially available DNA probes. Serological tests for antibodies are of limited use because of problems with sensitivity and specificity. An immunologic test for *B. dermatitidis* antigens in serum or urine is commercially available.

Blastomycosis tends to be chronic and progressive, and mortality rates as high as 90% have been reported. Thus, the current consensus is that all people with proven pulmonary or extrapulmonary blastomycosis should receive antifungal therapy. *B. dermatitidis* is susceptible *in vitro* to the polyene antifungal amphotericin B and to the azole antifungals ketoconazole, itraconazole, and fluconazole. Case series and/or formal treatment trials indicate that all of these treatments are effective. With treatment, most people with blastomycoses recover.

Histoplasmosis

Causative organism

The causative agent of histoplasmosis is *H. capsulatum*, the asexual form of the ascomycete *Ajellomyces capsulatum*. *H. capsulatum* is dimorphic in that it grows as a filamentous mold in the environment and in culture at $\leq 30^\circ\text{C}$ (Figure 2(a)), and it grows as small uninucleate budding yeast cells (diameter 3–5 μm) in infected tissues and in culture at 37°C (Figure 2(b)). The mold form of *H. capsulatum* produces both macroconidia (diameter 8–15 μm) and microconidia (diameter 2–5 μm). Microconidia are presumed to be the most important infectious particles because their small size allows them to reach the alveoli of the lung. *H. capsulatum* exists in two mating types (+ and –). Approximately equal proportions of the + and – mating types have been isolated from environmental sources such as soil, but most strains isolated from infected people are of the – mating type.

H. capsulatum var. *duboisii* causes histoplasmosis in central Africa. The mold form of this fungus is indistinguishable morphologically from North American *H. capsulatum* strains, but yeast-phase cells of *H. capsulatum* var. *duboisii* are much larger (diameter 10–15 μm).

Epidemiology

Histoplasmosis is endemic in the Eastern and Central United States, specifically in the Ohio River Valley and the lower Mississippi River Valley. Skin test surveys conducted in US military recruits in the 1940s established that as many as 80% of people who live in highly endemic areas have acquired immunity to *H. capsulatum*. The fungus can be found in high concentrations in soil contaminated with bird or bat droppings, caves, areas harboring bats, poultry housing litter, and bird roosts. Outbreaks in endemic areas have been traced to the disturbance of contaminated sites during large-scale excavations or construction projects. Sporadic cases have been diagnosed in people who have neither lived in nor visited endemic areas. *H. capsulatum* var. *duboisii* is endemic in central Africa.

Figure 2 *Histoplasma capsulatum* grows as a mold with hyphae, microconidia, and macroconidia at 25 °C (a), and it grows as small budding yeast cells at 37 °C (b). Large numbers of *H. capsulatum* yeast cells can often be demonstrated within mononuclear phagocytic cells of people with disseminated histoplasmosis, as in this specimen of bone marrow (c). Images courtesy of George Deepe, University of Cincinnati.

Pathogenesis and clinical features

Inhaled microconidia are deposited in the lungs and are ingested by resident phagocytic cells via receptor-mediated endocytosis. Conversion of microconidia to the yeast-phase form of growth is presumed to occur intracellularly. Once viable fungi are ingested by phagocytes, some are killed, whereas others survive and can replicate within the phagolysosomes of monocytic phagocytes. When the *H. capsulatum* yeast cells proliferate within infected host phagocytes, they eventually kill the cells and go on to infect adjacent phagocytic cells. Also, the yeast cells can disseminate to distant sites within infected host phagocytes. Fungal replication in the lungs or in other organs is eventually controlled by cellular immune mechanisms, which eventually results in the formation of dense granulomata. Acquired T-cell immunity to *H. capsulatum* develops and can be demonstrated by skin testing with crude *H. capsulatum* antigen mixtures and by *in vitro* lymphocyte stimulation studies. Adoptive transfer studies in mice have established that acquired immunity to *H. capsulatum* is protective.

A large majority of people who acquire histoplasmosis by inhalation are asymptomatic or they develop only minimal respiratory symptoms. Acute pulmonary histoplasmosis develops in a small minority of individuals following initial infection, especially when the initial fungal inoculum is large. This form of histoplasmosis is characterized by fever, malaise, chest pain, and nonproductive cough. Chest radiographs demonstrate progressive pneumonia (which is often diffuse and bilateral) and sometimes also regional lymphadenopathy. Most people with pulmonary histoplasmosis recover completely without therapy, so the only evidence of past infection is skin test reactivity and sometimes the presence in radiographs of multiple calcified granulomas in the lungs, spleen, or other organs.

Some people who recover from their initial pulmonary infections develop chronic pulmonary histoplasmosis. As this can occur many years after an individual has left the endemic area, this form of histoplasmosis (which closely resembles pulmonary tuberculosis) presumably results from reactivation of latent infection. Symptoms generally include cough, fever, and weight loss, and these symptoms can progress over the course of months to years. Chest radiographs usually show upper lobe pulmonary disease, often with cavity formation and scarring. Differentiating histoplasmosis from tuberculosis in patients such as these can be very challenging.

H. capsulatum can also cause disease in extrapulmonary sites. In people with profound defects with regard to cell-mediated immunity (e.g., patients with advanced acquired immunodeficiency syndrome (AIDS) or organ transplant recipients) or whose immune systems are immature (e.g., infants and young children), widely disseminated histoplasmosis can develop. This form of histoplasmosis can follow primary infection, or it can develop in previously infected people who develop immune deficiencies. This severe form of disseminated histoplasmosis is characterized by extensive proliferation of *H. capsulatum* yeast cells within phagocytic cells in the blood and in organs such as the spleen, liver, and bone marrow. People with this form of histoplasmosis are usually severely ill with a clinical syndrome that resembles generalized sepsis. Key clinical and laboratory features include fever, chills, enlargement of the liver and/or spleen, hematologic abnormalities including anemia, leukopenia, thrombocytopenia, and disseminated intravascular coagulation. This form of disseminated histoplasmosis is fatal if untreated.

A second form of disseminated histoplasmosis tends to occur in older individuals without known immunodeficiency states. This type of disseminated histoplasmosis varies widely in severity and pace; in some people the only symptoms are gradual weight loss and fatigue and in others there is clear evidence of the involvement of many different extrapulmonary organs (e.g., liver, spleen, meninges, adrenals, and bone marrow). One clue that the problem may be disseminated histoplasmosis is the presence of painful oropharyngeal ulcerations. These lesions usually have raised borders, and they are often mistaken for neoplasms. When biopsied, these lesions show a mix of acute inflammatory reactions and granuloma formation, and special stains generally reveal abundant small budding yeast.

H. capsulatum can also cause disease by eliciting inadequately attenuated host immune responses. In normal individuals, tissues respond to *H. capsulatum* cells or antigens by forming granulomata, which are often dense and fibrotic. In addition to limiting fungal replication and containing infection, this process can lead to the development of pulmonary nodules (histoplasmoses) that

sometimes enlarge to several centimeters in diameter. These nodules are often removed because they can be difficult to differentiate from neoplasms. Histopathological examination shows that these lesions are well-organized granulomas with prominent fibrosis; budding yeast cells are generally sparse or absent and cultures are usually negative. Another clinical and pathological entity associated with host responses to *H. capsulatum* antigens is mediastinal granulomatosis and fibrosis. This late complication of histoplasmosis of the mediastinal lymph nodes and adjacent structures is characterized by granuloma formation and dense fibrosis that results in the obliteration and obstruction of key structures, including the airways, esophagus, lymphatics, and blood vessels. Lymphocytic infiltrates and scars in the choroid and retina of the eye occur in people who live in areas in which histoplasmosis is endemic and is presumed to result from cellular immune responses to *H. capsulatum* antigens.

Infection by *H. capsulatum* var. *duboisii* (which causes African histoplasmosis) is presumably also via the lungs, but acute and chronic pulmonary disease is rare. Rather, this organism tends to cause skin, subcutaneous, and bone infections.

Diagnosis and treatment

Histoplasmosis is diagnosed definitively by isolating *H. capsulatum* in culture. Because the filamentous form of *H. capsulatum* cannot readily be distinguished from several other fungi, definitive identification of *H. capsulatum* formerly required its conversion of hyphal-phase organisms to the yeast phase by incubating the cultures at 37 °C or by animal inoculation. However, DNA probes that can definitively identify fungi as *H. capsulatum* are now available commercially. *H. capsulatum* grows slowly; so cultures generally may require several weeks of incubation before growth is detected. Moreover, cultures from some patients are often negative even after prolonged incubation. Thus, it is sometimes necessary to make a presumptive diagnosis of histoplasmosis by microscopy. Histological sections or appropriately stained smears of peripheral blood or other body fluids are examined for the presence of small yeast-like cells that bud from narrow bases. These fungi are generally sparse or absent in pulmonary nodules or in material obtained from patients with mediastinal fibrosis or with ocular histoplasmosis, but they are often easily demonstrated in tissues or body fluids from patients with the acute or chronic forms of disseminated histoplasmosis (Figure 2(c)).

As histoplasmosis can be difficult to diagnose by culture or direct microscopy, serologic testing is an important adjunctive method. Antibodies to yeast and mycelial antigens are generally detected by complement fixation (CF) and immunodiffusion (ID) tests. High or rising antibody titers can provide evidence of active or recent infection, but interpretation of serologic tests is confounded by delayed or absent responses in some people (especially immunocompromised hosts) and by the persistence of detectable antibodies for many years after active infection in some others. Immunologic tests for *H. capsulatum* antigens in serum, urine, bronchial lavage fluid, and cerebrospinal fluid (CSF) have been used to diagnose histoplasmosis in people with acute pulmonary, acute disseminated, and meningeal histoplasmosis. These tests are available in commercial reference laboratories and can provide rapid and specific diagnoses, although some cross-reactions have been described. In AIDS patients or others with disseminated histoplasmosis, serial serum or urine antigen determinations are useful in assessing responses to treatment.

H. capsulatum is susceptible *in vitro* to amphotericin B and to the azole antifungals ketoconazole, itraconazole, and fluconazole, and all of these drugs have been used with success in people with histoplasmosis. Antifungal chemotherapy is required only in forms of histoplasmosis in which fungal proliferation is a prominent feature, such as severe acute pulmonary histoplasmosis, chronic pulmonary histoplasmosis, and the acute or chronic forms of disseminated histoplasmosis. Antifungal therapy is of no value in patients with stable or enlarging pulmonary nodules, mediastinal granulomatosis and fibrosis, or ocular histoplasmosis.

Coccidioidomycosis

Causative organisms

Coccidioides immitis and *Coccidioides posadasii* are the causative agents of coccidioidomycosis. These are dimorphic ascomycetes that grow as filamentous molds and produce barrel-shaped arthroconidia in the environment and in culture. In infected tissues and in specialized liquid growth media, *Coccidioides* produces thick-walled structures called spherules, which reproduce by endosporeulation, a process by which the interior of the spherule is divided into as many as several hundred individual cells (endospores) (Figure 3). When the spherule ruptures, the individual endospores are released into the surrounding environment, and each spore is capable of generating a new spherule.

Sexual reproduction in *C. immitis* and *C. posadasii* has not been observed directly, but molecular genetic analyses of isolates collected from infected people and the environment support the view that meiotic recombination probably occurs in the environment.

Epidemiology

Coccidioidomycosis is endemic in arid regions in the southwestern United States, Mexico, and Central and South America. *C. immitis* is limited to the San Joaquin Valley in California and in parts of Arizona, whereas *C. posadasii* is more widespread in geographic distribution. The importance of environmental exposure to airborne spores is illustrated by new infections occurring most frequently in the dry seasons (late summer and early fall) and by large outbreaks of coccidioidomycosis occurring after dust storms, earthquakes, and other events that disturb and aerosolize the soil.

The importance of coccidioidomycosis has increased in recent decades as the population in arid regions of the southwestern United States has grown, especially with the influx of older retirees and immunocompromised individuals. In fact, new cases of coccidioidomycosis increased eightfold in several high-prevalence states between 1998 and 2011.

Pathogenesis and clinical features

The barrel-shaped arthroconidia of *C. immitis* and *C. posadasii* are highly infectious when they are inhaled into the lungs. Once they are deposited in the lung of a susceptible person, the arthroconidia swell and produce spherules that fill with endospores. The

Figure 3 *Coccidioides posadasii* spherules filled with endospores are typically seen in infected tissues. The fungus can be induced to form spherules *in vitro* in special synthetic medium at 37 °C in the presence of CO₂. Image courtesy of Garry Cole, University of Texas at San Antonio.

endosporulating spherules rupture and release their endospores, each of which can generate a new spherule. This process results in primary pneumonia, which is the most common clinical syndrome associated with coccidioidomycosis.

Approximately 60% of primary *Coccidioides* infections cause no or only minor symptoms and thus are recognizable only later by a positive skin test. Symptoms in the remaining patients with pulmonary infections range from mild to severe. In general, the symptoms are nonspecific and include cough, chest pain, fever, chills, headache, and night sweats. Chest radiographs usually show pneumonia or pleural effusions, with or without hilar or mediastinal lymphadenopathy. Immune-mediated skin lesions such as erythema nodosum or erythema multiforme can also occur in association with pulmonary coccidioidomycosis. Most cases of pulmonary coccidioidomycosis resolve without treatment, although a minority of patients who recover have residual abnormalities such as single or multiple pulmonary nodules or thin-walled cavities on their chest radiographs. That active coccidioidomycosis sometimes develops in people who left the endemic area many years earlier implies that some of these residual lesions contain dormant but still viable fungi that are capable of reactivating when immune surveillance fails.

In a minority of patients, pulmonary coccidioidomycosis progresses to a chronic form of pneumonia that can persist for months or even years. These infections usually resemble pulmonary tuberculosis in that the upper lobes are often involved, and there is often prominent granuloma formation, fibrosis, and cavity formation. Large pulmonary masses and military disease also occur. Histopathological examination of these chronic or persisting lung lesions often shows a combination of suppurative and granulomatous features.

In a small minority of individuals, disseminated coccidioidomycosis develops, either soon after the primary pulmonary infection or much later when latent infection reactivates. Risk factors for the development of disseminated coccidioidomycosis include traditional causes of immunodeficiency such as AIDS, organ transplantation, or therapy with corticosteroids or other immunosuppressive drugs. Disseminated coccidioidomycosis is also more common in people of African American and Filipino ancestry, in young children and the elderly, and in pregnant women. The most common sites of extrapulmonary involvement are the skin, subcutaneous tissues, bones and joints, and meninges, but almost any organ can be involved. Meningeal coccidioidomycosis commonly causes hydrocephalus that requires surgical shunting, and this form of coccidioidomycosis is very difficult to cure.

Diagnosis and treatment

The diagnosis of coccidioidomycosis is established by demonstrating spherules by microscopy in sputum, pleural fluid, or tissues or by isolating *Coccidioides* in cultures of clinical samples. Clinicians should warn laboratory staff when coccidioidomycosis is suspected because cultures of *Coccidioides* are hazardous. A DNA probe that can identify a fungal isolate as *Coccidioides* is available commercially, so it is no longer necessary to convert the hyphal form to spherules in culture or by animal inoculation.

Serologic tests for antibodies to *Coccidioides* antigens are often useful. Enzyme immunoassays (EIA) for IgM antibodies are very sensitive, but also give many false-positive results. EIA tests for IgG and ID tests for IgM and IgG antibodies to *Coccidioides* antigens are less sensitive, but more specific. The CF test is usually positive at titers of 1:16 or higher in patients with disseminated or severe infections and declines with successful therapy. As is the case with most other infectious diseases, patients with profound immunodeficiency (e.g., those with advanced AIDS) are less likely to have measurable humoral immune responses to *Coccidioides* than are patients who are immunologically intact.

Skin testing for delayed-type hypersensitivity to *Coccidioides* is useful mostly as an epidemiologic tool, and the reagents are no longer available commercially.

C. immitis and *C. posadasii* are susceptible *in vitro* to amphotericin B and to the azole antifungals fluconazole, itraconazole, and voriconazole. Patients with pulmonary nodules, asymptomatic patients with a pulmonary cavity, and patients with acute pneumonia who are not seriously ill can often be observed because many improve without therapy. Patients with severe or progressive pulmonary disease or with extrapulmonary disease are treated with an azole or with amphotericin B. Meningeal coccidioidomycosis is usually treated with high-dose fluconazole or intravenous plus intrathecal amphotericin B; some patients require surgical shunting because of obstructive hydrocephalus.

The prognosis in normal hosts with pulmonary coccidioidomycosis is generally good. The outcome is less favorable in patients with disseminated infection, those who have underlying immunodeficiency states, and those with meningeal coccidioidomycosis.

Paracoccidioidomycosis

Causative organism

The causative agent of paracoccidioidomycosis is *Paracoccidioides brasiliensis*, a dimorphic ascomycete that grows as a mold in the environment and in culture at $\leq 25^{\circ}\text{C}$ (Figure 4(a)) and as budding yeast in infected tissues and in culture at $\geq 35^{\circ}\text{C}$. One unique feature of yeast-phase *P. brasiliensis* is that single large mother cells can generate multiple small daughter cells (Figure 4(b)).

Epidemiology

Paracoccidioidomycosis is restricted to Central and South America, between latitudes 23°N and 34°S . Within this region, the disease is common in some areas and almost never observed in others. Favorable environments are characterized by the presence of tropical or subtropical forests, abundant rainfall and water, and moderate temperatures.

Skin test surveys show that approximately equal number of males and females have been exposed to *P. brasiliensis*, but many more males than females develop clinical disease. Paracoccidioidomycosis is unusual in children; so this is primarily a disease of adult men, most of whom are agricultural workers.

Pathogenesis and clinical features

Infection is presumed to follow the inhalation of conidia produced in the environment by the filamentous form of *P. brasiliensis*. Once the conidia are deposited in the lung, they transform into yeast cells, they begin to proliferate, and they can disseminate to distant sites via the bloodstream and lymphatic system. The fungi initially elicit an intense inflammatory reaction. With time, granulomas form and fungal replication ceases. As some patients develop active paracoccidioidomycosis years after they have left the endemic areas, it is likely that at least some fungi within granulomas or other lesions are dormant but still viable and can thus reactivate when host immunity wanes or becomes insufficient.

Figure 4 *Paracoccidioides brasiliensis* grows as hyphae at 25°C (a) and as large yeast cells that produce multiple buds per cell at 37°C (b). Images courtesy of Paulo Coelho, University of Sao Paulo, Brazil.

Most primary pulmonary infections are asymptomatic or cause only minimal symptoms and are recognized only in retrospect because of positive skin test reactivity. The most common clinical syndrome caused by *P. brasiliensis* is a chronic infection of the lungs and one or more extrapulmonary sites. This form of paracoccidioidomycosis tends to occur in adult males and is characterized by a chronic, progressive pneumonia that usually involves the central and lower portions of both lungs. The most common extrapulmonary sites involved are the skin and oropharyngeal or laryngeal mucosa, both of which develop ulcers characterized by granuloma formation and presence of large numbers of yeast-phase *P. brasiliensis* cells. Lymph nodes, the adrenal glands and the central nervous system (CNS) are also often involved in this form of disease.

A second form of disseminated paracoccidioidomycosis occurs primarily in children and in immunocompromised hosts (e.g., patients with advanced AIDS). This form of paracoccidioidomycosis resembles severe disseminated histoplasmosis in that large numbers of fungi are present in multiple organs such as the liver, spleen, and lymph nodes. Lung disease is much less prominent in patients with this type of paracoccidioidomycosis than in immunologically normal adults with more chronic paracoccidioidomycosis.

Diagnosis and treatment

Yeast-phase cells of *P. brasiliensis* are usually abundant in infected body fluids and tissues; so the diagnosis is usually established by demonstrating typical multiply budding yeast cells in potassium hydroxide preparations of appropriate clinical specimens or in histological sections. *P. brasiliensis* can also be identified in culture, but it generally takes several weeks to obtain hyphal-phase growth and then to convert the mold to yeast-phase cells by shifting to 36–37 °C.

Serologic tests for antibodies are useful in paracoccidioidomycosis. Antibodies can be demonstrated by ID in as many as 95% of patients with active disease. The CF test is somewhat less sensitive, but the ability to quantify the antibody response by generating titers is useful for monitoring responses to treatment. Immunologic tests for *P. brasiliensis* antigens in serum and CSF have been described, but these tests are not widely available.

P. brasiliensis is susceptible to sulfonamides, amphotericin B, and the azoles ketoconazole and itraconazole, and all of these drugs have been effective in clinical studies. Therapy with sulfonamides for 3–5 years is safe, inexpensive, and effective in approximately 70% of cases. Amphotericin B and ketoconazole are also effective in approximately 70% of cases, and itraconazole for 6 months is effective in as many as 95% of cases.

Sporotrichosis

Causative organism

The causative agent of sporotrichosis is *Sporothrix schenckii*, a dimorphic fungus that grows as a filamentous mold in the environment and in culture at 25–27 °C and as small, elongated ‘cigar-shaped’ yeast cells (3–5 µm) in infected tissues and in culture at 37 °C.

Epidemiology

S. schenckii is found throughout the world, especially in soil and in decaying or live plant matter. Most infections result from inoculation of hyphal-phase fungi through the skin at the sites of minor injury; so infections are most common in people who handle plants or plant products (e.g., gardeners and agricultural workers). *S. schenckii* can also be transferred from soil to people by infected or contaminated animals (e.g., cats). Several outbreaks have been described, including a large outbreak in South African mine workers who handled contaminated timber and outbreaks associated with contaminated plant materials used for gardening.

Pathogenesis and clinical features

The most common form of sporotrichosis is lymphocutaneous disease. This form of sporotrichosis follows inoculation of hyphal material through minor injuries in the skin. The fungus converts to yeast-phase cells, and the host responds by mounting an inflammatory reaction that includes neutrophils and also mononuclear phagocytes. Several days to a few weeks later, a papule or nodule usually develops, and then similar nodules develop over several weeks along the course of the lymphatics that drain the site of initial injury. Some of these nodules ulcerate and drain. The lesions are usually not painful.

Less common forms of sporotrichosis include pulmonary infection that closely resembles pulmonary tuberculosis, arthritis or osteomyelitis, and meningitis. Disseminated sporotrichosis has been described in patients with advanced AIDS and in patients who have received tumor necrosis factor antagonists.

Diagnosis and treatment

Definitive diagnosis of sporotrichosis requires that the causative fungus be isolated in culture and then converted from its hyphal phase to the characteristic yeast-phase cells. Because this generally takes several weeks, a presumptive diagnosis can be made if microscopic examination of appropriate fluids or tissues reveals typical elongated budding yeast cells. Unfortunately, these cells can be sparse and difficult to find. Serologic tests for sporotrichosis are generally not available, and there are no tests for *S. schenckii* antigens.

Most patients with lymphocutaneous, pulmonary, or bone and joint sporotrichosis can be treated effectively with itraconazole for at least several months. Potassium iodide by mouth is also effective in lymphocutaneous sporotrichosis; the mechanisms by which this treatment works are unknown. Amphotericin B can be used as initial therapy in people with *S. schenckii* meningitis or in immunocompromised patients with widely disseminated disease.

Diseases Caused by Opportunistic Fungi

Candidiasis

Causative organisms

Candidiasis refers to infections caused by fungi in the genus *Candida*. Together, these organisms are the most common causes of serious fungal infections in people. The most important pathogenic *Candida* species are *C. albicans*, *Candida glabrata*, *Candida tropicalis*, and *Candida parapsilosis*. All of these organisms grow in infected tissues and in culture as budding yeast-like fungi, and all except for *C. glabrata* can also form elongated buds (pseudohyphae). *C. albicans* and some strains of *C. tropicalis* can also form hyphae (Figure 5). The pathogenic *Candida* species are generally differentiated from each other based on (1) the abilities of *C. albicans* (and its close relative *Candida dubliniensis*) to form hyphae (also called germ tubes) when incubated in serum or other protein solutions, (2) the production of distinctive colors on indicator media (e.g., ChromAgar), (3) carbohydrate assimilation and fermentation patterns, and (4) morphologic features when grown in nutrient-limiting media.

C. albicans was once responsible for a substantial majority of serious *Candida* infections, but the importance of other *Candida* species has increased in recent decades. This trend was first noted in the 1970s and 1980s in cancer patients and bone marrow transplant recipients, and it has recently been documented in unselected populations. For example, a recent study of all *Candida* bloodstream infections in Baltimore County, Maryland, and in Connecticut between 1998 and 2000 showed that *C. albicans* was the causal agent in 45% of cases, *C. glabrata* in 24%, *C. parapsilosis* in 13%, *C. tropicalis* in 12%, and other *Candida* species in 6%.

One insight that emerged from sequencing of the genomes of several *Candida* species is that these fungi have mating loci that resemble the mating loci in ascomycetes with known sexual reproductive cycles. This led to the recognition that diploid *C. albicans* strains that were homozygous for the *MTL a* or the *MTL α* mating locus can mate with homozygous strains of opposite mating type to form tetraploid cells, which then return to diploidy by chromosome loss. Whether and how often events like this occur in natural populations of *Candida* cells is not known, but these observations raise the possibility that pathogenic eukaryotes that have lost the ability to grow as haploids or to undergo meiosis can acquire alternative mechanisms for genetic recombination.

Epidemiology

The epidemiology of candidiasis differs from the epidemiology of most other fungal diseases because normal people are colonized by *Candida*. Thus, candidiasis is acquired from endogenous sources rather than by exposure to fungi in the environment. Among the major *Candida* species, *C. albicans*, *C. tropicalis*, and *C. glabrata* populate the gastrointestinal tract and vagina of normal individuals, and *C. parapsilosis* is often found on the skin. Consequently, symptomatic infections generally develop when these fungi overgrow at sites of colonization (often as a consequence of suppression of the competing bacterial flora because of antimicrobial therapy) and when the host's defenses against infection are diminished.

Pathogenesis and clinical features

There are two general patterns of candidiasis. In people in whom overgrowth of *Candida* occurs because of suppression of competing bacterial flora by antibiotics or defects in cell-mediated immunity (e.g., corticosteroid recipients and patients with advanced HIV infection), the predominant form of disease is mucosal or cutaneous candidiasis. Typical mucosal lesions consist of white plaques that overlie shallow ulcers on an erythematous base. The ulcers are often filled with inflammatory cells and a mixture of *Candida* yeast cells and pseudohyphae, and the base may bleed if the white plaque is scraped off. Mucosal candidiasis of the mouth and pharynx is referred to as thrush, and similar lesions can occur anywhere in the gastrointestinal tract. Similar lesions also occur in the vagina. Finally, *Candida* can also infect the skin (especially in moist areas where skin maceration has occurred) and the fingernails and toenails (especially in patients with cell-mediated immune deficiency).

The second form of candidiasis is characterized by the fungal invasion of deeper organs and is generally referred to as disseminated or systemic candidiasis. In this form of candidiasis, the fungus usually enters the bloodstream through the gastrointestinal tract or vagina and the major risk factors are loss of mucosal integrity and lack of functional neutrophils. In recent years

Figure 5 *Candida albicans* can grow as budding yeast (a), yeast cells with elongated buds called pseudohyphae (b), or as true hyphae (c). Short hyphal cells shown in (c) are also known as germ tubes.

bloodstream infections occur more commonly via an intravascular device such as an intravenous catheter. *Candida* invades distant organs by (1) adhering to the vascular endothelium, (2) exiting from the vascular space into surrounding tissues, (3) proliferating within those tissues, and (4) eliciting an intense inflammatory reaction. The cardinal feature of this form of candidiasis is the presence of multiple microabscesses within many different tissues. Most patients with disseminated candidiasis are febrile and have signs of generalized infection, but specific clues that the problem is caused by *Candida* are usually lacking.

Hepatosplenic candidiasis is characterized by the onset of fever, abdominal pain, and biochemical evidence of hepatic dysfunction when patients whose bone marrow function is depressed by cytotoxic drugs and/or radiation therapy recover the ability to mount an inflammatory response and thereby respond to *Candida* cells that previously seeded the liver and spleen. In addition to these more generalized syndromes, *Candida* species can also cause deep infections in individual organs, such as bones, meninges, retina and adjacent structures in the eye, and heart valves. Involvement of organs such as these generally develops as a complication of *Candida* fungemia, although the fungemic event may be unapparent or unrecognized.

Diagnosis and treatment

Candida infections can be diagnosed by demonstrating fungal cells with characteristic morphology by microscopy or by culturing the organisms from appropriate sites. Microscopic or microbiologic demonstration of *Candida* species from superficial body surfaces (e.g., skin, mucosal surfaces, and sputum) does not imply infection because *Candida* species are part of the normal commensal flora. Whether *Candida* is causing or contributing to mucosal or cutaneous disease generally must be determined by considering the number of fungi observed, the type of lesions, and relevant host factors. On the other hand, isolation of *Candida* species from body fluids such as blood or CSF or from biopsies of deep tissues constitutes strong evidence of invasive infection. However, at least 50% of patients with disseminated candidiasis have repeatedly negative blood cultures, and there are no reliable nonculture diagnostic methods. Consequently, the diagnosis of disseminated candidiasis is often delayed or missed.

Serologic tests for antibodies to *Candida* species are not useful because normal people have detectable antibodies to this commensal organism. There have been extensive efforts to develop tests for distinctive *Candida* antigens and nucleic acids, but none of these is generally available or used. Several pathogenic *Candida* species produce sufficient amounts of the 5-carbon sugar alcohol D-arabitol in infected tissues and serum and urinary levels of this compound are elevated in a majority of patients with disseminated candidiasis. D-arabitol is used as a diagnostic marker in Japan and Scandinavia, but these tests are generally not available in North America.

Most strains of the medically important *Candida* species are susceptible *in vitro* to amphotericin B, the azole antifungals (e.g., fluconazole, itraconazole, and voriconazole), and the echinocandins (casposungin, micafungin, and anidulafungin). Clinical trials conducted mostly in AIDS patients with esophageal candidiasis and in patients with *C. fungemia* have established that antifungals in all of these classes are effective. Most trials in patients with *Candida* fungemia or other forms of invasive *Candida* infections have shown that these classes of drugs have similar efficacies, but a recent pooled analysis of multiple studies suggest that echinocandins may be more effective than fluconazole. Resistance to azole antifungals can develop in people who are heavily treated for prolonged periods, and some *Candida* species are inherently more resistant to some classes of antifungals than most others (e.g., *C. glabrata* and azoles, *C. parapsilosis* and echinocandins).

Most patients with mucosal or cutaneous candidiasis can be treated effectively with topical antifungals or systemic azoles. Despite the availability of multiple effective antifungals, disseminated candidiasis remains a serious infection. Attributable mortality rates in the range of 35–50% have been reported, and these have not changed substantially in recent decades.

Cryptococcosis

Causative organisms

Cryptococcosis refers to infections caused by fungi in the genus *Cryptococcus*, which are the asexual forms of basidiomycetes in the genus *Filobasidiella*. A unique feature of *Cryptococcus* is that these are the only medically important fungi that have thick polysaccharide capsules, which consist of chains of α 1,3-linked mannose units with xylosyl and β -glucuronyl substitutions. Human cryptococcosis is mostly caused by *C. neoformans*, of which there are two varieties (var. *neoformans* (serotype D) and var. *grubii* (serotype A)). *Cryptococcus gattii* (formerly called *C. neoformans* serotypes B and C) is responsible for approximately 5% of all cases of cryptococcosis, especially in several geographically restricted areas (see below).

All pathogenic *Cryptococcus* species grow as encapsulated budding yeast in infected people and in culture. When haploid cells of opposite mating types (α or α) are mixed on nutrient-limiting media, mating generates diploid hyphal forms that produce clamp connections and basidia, and haploid basidiospores are produced as a result of meiosis. Filamentation and formation of basidia and basidiospore formation can also be induced by nutrient deprivation in haploid cells of a single mating type. Although mating and basidiospore formation have not been observed in nature, molecular genetic analyses of environmental and pathogenic strains provide strong indirect evidence that sexual recombination occurs.

One surprising observation is that almost all strains isolated from infected people and also a large majority of environmental isolates are of mating type α . Moreover, direct comparison of the virulence in animals showed that a *C. neoformans* mat α strain was much more virulent than a congenic α strain. Classical and molecular genetic studies have also established that the ability to grow at 37 °C to form melanin and capsules is required for wild-type virulence.

Epidemiology

C. neoformans is found throughout the world, especially in soil and other material that are heavily contaminated with bird (especially pigeon) feces. Some areas have much higher incidence and prevalence rates than others, which presumably reflects differences in environmental conditions and factors such as bird populations. *C. neoformans* infections were once quite uncommon,

tending to occur almost exclusively in people with cellular immunodeficiency states caused by neoplasia, organ transplantation, and administration of immunosuppressive drugs. However, the HIV epidemic has greatly expanded the population at risk for serious *Cryptococcus* infections. Cryptococcosis is now a leading cause of death among people with AIDS in Africa and elsewhere in the developing world.

C. gattii is primarily found in tropical and subtropical areas, often in association with trees (especially eucalyptus) and their surrounding microenvironments. However, a large cluster of cases of human and animal *C. gattii* infections was recently recognized on Vancouver Island in Western Canada, and this epidemic has since spread to the mainland of British Columbia, Washington, and Oregon. One unexpected aspect of this ongoing epidemic is that there is molecular genetic evidence that a hypervirulent epidemic strain may be the product of a sexual cross between a nonvirulent strain endemic and another strain that was recently introduced into this area. *C. gattii* causes serious pulmonary and extrapulmonary disease in immunologically normal hosts; so the epidemiology of *C. gattii* and *C. neoformans* diseases differs substantially. Since this epidemic of *C. gattii* infections in Western Canada and the Pacific Northwestern USA was recognized, additional cases have been documented in many additional geographic areas around the world.

Pathogenesis and clinical features

Cryptococcus is acquired by inhaling viable fungi in the environment into the lungs. Whether the infectious particles are desiccated yeast cells or basidiospores is not known. Once the fungi are deposited in the lungs, they proliferate as budding yeast cells, and the infection is usually controlled by the combined activities of natural and acquired host defenses. Neutrophils, mononuclear phagocytes, and lymphocytes all participate in cellular defenses against *Cryptococcus*, and phagocytosis and killing are also enhanced by humoral immune molecules such as antibodies to the capsular polysaccharide and its complements.

Most cases of pulmonary cryptococcosis are asymptomatic or result in only minor symptoms, and they resolve spontaneously without sequelae. In a minority of normal people and more often in people with cell-mediated immune deficiency, primary infection with *Cryptococcus* can lead to significant pulmonary disease. Symptoms can include cough, fever, chest pain and dyspnea, and chest radiographs can reveal pneumonitis, pulmonary nodules that may cavitate, pleural effusions, and regional lymphadenopathy.

Dissemination to extrapulmonary sites is common, especially in immunodeficient hosts. Extrapulmonary disease can develop at the same time or shortly after a patient has pulmonary cryptococcosis, but most cases occur without concomitant pulmonary disease. The most important extrapulmonary manifestation of cryptococcosis is meningoencephalitis, which is usually subacute or chronic. Patients with CNS cryptococcosis usually have headache, fever, and signs of meningeal irritation. Mental function abnormalities are common and can range in severity from subtle memory loss or personality changes to profound obtundation and coma. Cranial nerve dysfunction is common and often results from increased intracranial pressure. The pace and severity of CNS cryptococcosis can be highly variable. Some patients progress to coma and death within a few days, whereas others have had untreated chronic cryptococcal meningitis for >10 years.

Other extrapulmonary manifestations of cryptococcosis include mass lesions in the CNS (cryptococcomas), nodular skin lesions, chronic prostatitis, and bone lesions. Diffuse bilateral pulmonary disease that resembles miliary tuberculosis or *Pneumocystis* pneumonia can also occur in profoundly immunodeficient people.

Diagnosis and treatment

Cryptococcosis can be diagnosed by demonstrating encapsulated budding yeast cells in clinical specimens or in histological sections, by isolating the causative fungus in culture, or by demonstrating capsular polysaccharide antigens by immunoassay. As *Cryptococcus* is the only pathogenic fungus with a capsule, microscopic demonstration of encapsulating budding yeast cells in body fluids or tissues is diagnostic of cryptococcosis. The capsule of *Cryptococcus* is easily demonstrated in specimens such as CSF by its ability to exclude India ink (Figure 6). The capsule can appear as a clear halo around yeast cells in histological sections, and it is stained by mucicarmine. *C. neoformans* and *C. gattii* are usually isolated in culture within 2–3 days from CSF, blood, respiratory specimens, or tissue biopsies. Positive cultures can be identified as *Cryptococcus* by demonstrating the polysaccharide capsule, by India ink staining, or by immunoassay. Type-specific sera for differentiating *C. neoformans* from *C. gattii* are generally not available; however, *C. gattii* produces blue pigment on canavanine–glycine–bromothymol blue agar, and *C. neoformans* does not.

Several immunoassays are available for demonstrating the capsular polysaccharide of *C. neoformans* and *C. gattii* in body fluids. These tests are now highly sensitive and specific, and they can be used with CSF, blood, and bronchial lavage fluids. Among all the immunoassays for fungal antigens, the test for cryptococcal polysaccharide is the most reliable and widely used.

C. neoformans is susceptible *in vitro* to amphotericin B, the combination of amphotericin B and flucytosine, and the azole antifungals fluconazole and itraconazole. Clinical trials have established that all of these therapies are effective in patients with cryptococcal meningoencephalitis. In contrast, the echinocandins have no activity against *Cryptococcus* and should not be used. Combination therapy with amphotericin B and flucytosine sterilizes the CSF faster, and is associated with fewer late relapses and lower mortality than is therapy with amphotericin B or fluconazole alone. Relapses following initial course of therapy are common in AIDS patients and others whose underlying immunodeficiency cannot be corrected; so prolonged maintenance therapy with fluconazole is often required. Marked worsening of intracranial hypertension often occurs shortly after therapy is begun; so careful monitoring for this complication and prompt intervention are mandatory.

No formal treatment trials have compared different therapies in patients with nonmeningeal cryptococcosis. Also, *C. gattii* appears to be less susceptible to azole antifungals than *C. neoformans*, but whether patients with serious *C. gattii* infections should be treated with amphotericin B, amphotericin B plus flucytosine, or an azole antifungal has not been studied.

Figure 6 *Cryptococcus neoformans* produces a polysaccharide capsule, which is demonstrable as a clear halo surrounding cells in this India ink preparation. Image courtesy of Kausik Datta, Oregon Health & Science University.

Penicilliosis

Causative organism

Penicilliosis refers to diseases caused by fungi in the genus *Penicillium*. The most important *Penicillium* species is *Penicillium marneffei*, which causes serious infections in immunocompromised individuals in Southeast Asia. *P. marneffei* is a dimorphic fungus that grows as hyphae at 25–30 °C and as a yeast at 37 °C. Hyphal-phase *P. marneffei* produces a red pigment that diffuses into agar culture medium. Yeast-phase *P. marneffei* cells divide by fission (i.e., schizogony, as does the model fungus *Schizosaccharomyces pombe*) rather than by budding.

Epidemiology

P. marneffei is endemic in Southeast Asia. Cases of human disease have been reported in Thailand, Laos, Cambodia, Vietnam, Malaysia, Singapore, Burma, Taiwan, and Southern China. The organism has been isolated from healthy bamboo rats and from soil in and around these animals' burrows. Retrospective case–control studies have associated *P. marneffei* infection with exposure to soil and not with exposure to bamboo rats.

P. marneffei causes disease almost exclusively in people with profound abnormalities of cell-mediated immunity. Advanced HIV infection is the most common underlying condition, but cases are also observed in people with hematologic neoplasia, in organ transplant recipients, and in people receiving immunosuppressive drugs. *P. marneffei* infection is the third most frequent serious opportunistic infection among AIDS patients in Northern Thailand, following only tuberculosis and cryptococcosis.

Pathogenesis and clinical features

It is likely that infection is by inhalation of environmental spores, but this has not been proven. Most susceptible people with *P. marneffei* infections develop a subacute to chronic disseminated disease characterized by several weeks of fever, weight loss, and malaise. Many patients also have cough and other symptoms of lung infection, and a majority have skin lesions. These skin lesions are generally located on the face and upper body, and they can include papules (sometimes umbilicated), pustules, ulcers, or abscesses. At autopsy, there is usually widespread involvement of many organs, including the lungs, lymph nodes, bone marrow, liver, spleen, kidney, bowel, adrenals, bone, and meninges. Tissue reactions can include granulomatous and acute inflammatory reactions, often with necrosis or suppuration. Yeast-phase forms of *P. marneffei* are usually abundant in infected tissues.

Diagnosis and treatment

In endemic geographic locales, disseminated *P. marneffei* infection should be considered whenever an immunocompromised patient has a subacute to chronic progressive illness consistent with penicilliosis. In nonendemic areas, a history of prior residence or travel to an endemic area should be sought, especially since recrudescence years after departure from an endemic area has been documented.

Once the diagnosis of penicilliosis is considered, it is verified by demonstrating the causative organism in body fluids or tissues by microscopy or by culture. The diagnosis can often be established by demonstrating typical fungal forms in smears of skin biopsies, lymph node biopsies, or bone marrow aspirates or biopsies. If there is pulmonary involvement, the fungus can often be demonstrated by microscopic examination of respiratory secretions or bronchoalveolar lavage. *P. marneffe* can be isolated in culture from infected body fluids or tissues, including the blood, bone marrow, skin lesions, lymph nodes, sputum, or bronchoalveolar lavage, or other tissues. If hyphal-phase fungi with morphologic features typical of *Penicillium* species are isolated, identification of the organism as *P. marneffe* is established by conversion to yeast-phase growth by incubating at 37 °C.

Tests for distinctive antibodies to *P. marneffe* or for *P. marneffe* antigens or nucleic acid sequences are under investigation, but they are not generally available. *P. marneffe* has been reported to cross-react with tests for *Aspergillus* galactomannan.

P. marneffe is susceptible *in vitro* to amphotericin B, itraconazole, ketoconazole, and voriconazole, but not to fluconazole. Seriously ill patients are generally treated with intravenous amphotericin B initially (e.g., for 2 weeks) and then with itraconazole for at least 10 more weeks. Therapy with itraconazole alone is generally reserved for people with less severe disease. Relapses among AIDS patients with penicilliosis are common; so long-term suppression with itraconazole or fluconazole is often given. Whether treatment can be stopped if immune reconstitution is achieved with antiretroviral therapy is not known.

Aspergillosis

Causative organisms

The ascomycetous fungi in the genus *Aspergillus* are the causative agents of aspergillosis. These environmental molds are present in abundant amounts in many outdoor and indoor environments. *A. fumigatus* is by far the most important pathogen of humans. *Aspergillus flavus*, *Aspergillus niger*, *Aspergillus terreus*, and *Aspergillus lentulus* also cause serious infections. All of these fungi grow in the environment and in culture as branching hyphae, and they also produce airborne conidia (Figure 7).

Epidemiology

People are exposed to spores of *A. fumigatus* and other *Aspergillus* species on a regular basis; so whether exposure to these fungal spores results in disease is determined primarily by host susceptibility. Cases of invasive aspergillosis have increased markedly in recent decades, which is no doubt due to an increase in the number of people with markedly abnormal host defenses. In one study, cases of aspergillosis per 100 000 people in the United States increased more than fourfold between 1981 and 1997.

Although host susceptibility determines in large measure who acquires aspergillosis, environmental factors are also important. Several studies have documented outbreaks of cases among immunocompromised people who were exposed to aerosols generated by construction projects either within hospital buildings or outdoors. It has long been known that removal of airborne particles by high-efficiency air filtration can substantially reduce the incidence of aspergillosis among highly susceptible hosts.

Pathogenesis and clinical features

Aspergillus causes several different types of human disease. Allergic bronchopulmonary aspergillosis (ABPA) is characterized by chronically recurring episodes of bronchospasm associated with sputum production, mucus plugging of airways with resulting atelectasis, sometimes resulting in pulmonary to fibrosis and/or bronchiectasis. This syndrome is caused by hypersensitivity to antigens expressed by fungi colonizing the airways. Most patients with ABPA have high circulating levels of total IgE, demonstrable IgE-mediated responses to *Aspergillus* antigens, and high circulating levels of IgG antibodies to *Aspergillus* antigens. The course is generally chronic and progressive. Patients generally do not improve without therapy.

Aspergillus can also colonize anatomically abnormal airways, thereby initiating a local inflammatory reaction. When this occurs in residual cavities in patients with healed tuberculosis, a mass of fungal hyphae and necrotic debris that eventually fills the cavity is

Figure 7 *Aspergillus fumigatus* and other *Aspergillus* species grow in infected tissues and in culture as narrow septate hyphae that branch at angles of approximately 45° (a) *A. fumigatus* produces airborne asexual spores (conidia) from columnar fruiting bodies when cultured on agar plates (b) but these structures are seldom seen in infected mammalian tissues.

referred to as an aspergilloma or fungus ball. Most aspergillomas cause no symptoms, but they erode the surface of the cavity, which can result in bleeding (hemoptysis) that can be severe. *Aspergillus* can similarly colonize bronchiectatic airways of patients with underlying chronic lung diseases such as cystic fibrosis.

Invasive pulmonary aspergillosis is the form of aspergillosis that has increased markedly in frequency and importance in recent decades. Patients at highest risk include people with prolonged neutropenia due to stem cell transplantation or cytotoxic chemotherapy for neoplasia. Transplant recipients and patients receiving high doses of corticosteroids or other immunosuppressive drugs are also at increased risk. When an immunodeficient host inhales viable *Aspergillus* conidia, the fungi evade ingestion and killing by host phagocytes, they swell and germinate to produce filamentous hyphae, and they invade the surrounding tissues. *Aspergillus* tends to invade and proliferate within blood vessels, thereby causing ischemic injury and widespread necrosis in affected tissues. Patients with invasive pulmonary aspergillosis usually have fever and cough, and pleuritic chest pain is often present. Chest radiographs show pulmonary infiltrates that are often peripheral and wedge-shaped, as would be expected in a lesion in which vascular ischemia is an important contributor. Cavity formation is common and can be a valuable clue to the diagnosis. Disease progression is often very rapid in profoundly immunocompromised individuals, often leading to respiratory failure and death in a few days. In others (especially those with less severe immune deficiencies), the pace of the disease is much slower; chronic progression with formation of multiple cavities can develop over several months.

Aspergillus can also cause necrotizing sinusitis in some profoundly immunocompromised individuals. The initial site of infection is the mucosal surface of a facial sinus or the nasopharynx, which is directly invaded by germinating fungal hyphae. Because *Aspergillus* tends to invade blood vessels and thereby causes extensive tissue necrosis, this process can rapidly extend into the orbit and into the cranium. For unknown reasons, *A. flavus* is especially likely to cause necrotizing sinusitis.

Aspergillus can also disseminate to distant organs via the bloodstream in patients who have primary aspergillosis of the lung or a facial sinus. Once the fungus reaches these distant organs, it tends again to invade along blood vessels, thereby causing ischemia and tissue necrosis. Virtually any organ can be involved, including the brain, kidneys, liver, spleen, and skin.

Diagnosis and treatment

Aspergillus grows in infected tissues as narrow septate hyphae that branch at 30–45° angles, thus demonstrating fungi with these morphologic features in body fluids of tissues from a person with a compatible clinical syndrome can provide presumptive evidence of aspergillosis. However, the hyphae of several other pathogenic fungi (e.g., *Fusarium*) are similar in morphology; so a definitive diagnosis of aspergillosis requires both demonstration of the fungus in infected body fluids and/or tissues and isolation and identification of the fungus in culture. Interpreting the results of fungal cultures (especially from respiratory sites) can be difficult because (1) *Aspergillus* can colonize the respiratory tract without causing invasive disease and (2) some patients with proven invasive infections have repeatedly negative cultures. It should also be noted that *Aspergillus* is almost never isolated from blood, even in patients with widely disseminated disease.

Patients with ABPA usually have high total IgE levels and high levels of *Aspergillus*-specific IgE and IgG antibodies. Patients with aspergillomas or fungal colonization of bronchiectatic airways often have high levels of IgG antibodies to *Aspergillus* antigens. Serologic testing for antibodies to *Aspergillus* is not useful in invasive pulmonary or extrapulmonary aspergillosis. However, galactomannan derived from the cell wall of *Aspergillus* can be detected by immunoassay in a substantial portion of patients with invasive pulmonary or extrapulmonary aspergillosis, and galactomannan can be detected by immunoassay in bronchoalveolar lavage fluids from a substantial majority of patients with invasive pulmonary aspergillosis.

Growth of *Aspergillus* is inhibited *in vitro* by amphotericin B, the azoles itraconazole, voriconazole, and posaconazole (but not fluconazole or ketoconazole), and the echinocandins caspofungin, micafungin, and anidulafungin. Prospective clinical trials have established that itraconazole is an effective therapy for ABPA and that voriconazole is superior to amphotericin B for invasive aspergillosis. Uncontrolled studies suggest that caspofungin may be useful in patients who do not respond to or cannot tolerate alternative therapies. Controlled trials showed that posaconazole can prevent invasive aspergillosis in selected high-risk patients. Despite the availability of effective therapies, mortality in severely immunocompromised hosts with invasive aspergillosis remains very high. For this reason, there is considerable interest in combination chemotherapy, adjuvant immunotherapy, and other measures. Also, some patients with extensive necrotizing aspergillosis lesions may benefit from surgical debridement or resection, either to control the infection initially or to reduce the likelihood of relapse.

Zygomycosis

Causative organisms

The term zygomycosis refers to diseases caused by filamentous fungi in the class Zygomycota, the most important of which are in the genera *Rhizopus*, *Mucor*, and *Absidia*. As these fungi are in the order Mucorales, an alternative name for zygomycosis is mucormycosis. These fungi are widespread in nature. They can commonly be found in the soil and on decaying plant and animal matter; for example, zygomycetes include common bread molds. These fungi grow as molds consisting of broad hyphae that usually lack nonseptae. In the environment (but not in infected tissues), fruiting structures (sporangia) develop, which generate large numbers of airborne spores (sporangiospores). Consequently, most people regularly come in contact with airborne zygomycete sporangiospores.

Pathogenesis and clinical features

Most patients with zygomycosis have abnormal host defenses, although these often differ from those that underlie most other opportunistic mycoses. For example, the most important factor associated with zygomycosis is diabetes, especially with

ketoacidosis. Other forms of metabolic acidosis (e.g., uremia) also predispose to zygomycosis, as do states associated with availability in tissues of excess amounts of free iron (e.g., hemochromatosis or administration of iron-chelating agents). Corticosteroids, neutropenia, and interrupted skin (e.g., in burns or surgical incisions) are also important predisposing factors.

The most common form of zygomycosis is rhinocerebral zygomycosis, which begins when fungal spores deposit on the mucosal surfaces of the nasopharynx or palate. The spores then germinate into hyphae, which invade and then grow within blood vessels, thereby causing extensive thrombosis, ischemia, and necrosis. Zygomycosis typically breaches anatomical barriers and promptly involves the facial sinuses, the orbit and its contents, and then the cranial contents. Pain, swelling and cranial nerve palsies are often seen early, followed by frank skin necrosis, blindness, stupor, and coma.

In patients such as neutropenic stem cell transplant recipients and leukemia patients, inhalation of zygomycetes spores into the lungs can lead to pulmonary zygomycosis, which is very similar in its clinical and pathologic features to pulmonary aspergillosis. As is also observed in rhinocerebral disease, the zygomycetes invade and then grow along blood vessels in the lungs, causing extensive thrombosis, ischemia, and tissue infarction. Most patients have fever, cough, and/or chest pain, and chest radiographs usually show diffuse pneumonia, more focal disease that may cavitate, and/or pleural effusions.

Dissemination via the bloodstream to distant organs occurs in patients with either the rhinocerebral or pulmonary forms of zygomycosis, especially in patients with prolonged neutropenia or in stem cell transplant recipients. The zygomycetes also cause necrotizing skin infections, either as a secondary manifestation of widespread hematogenous dissemination or when viable spores are introduced into burn wounds or surgical incisions via contaminated wound dressing materials. The zygomycetes rarely cause invasive disease of the gastrointestinal tract, especially in malnourished children in the developing world.

Diagnosis and treatment

Most cases of zygomycosis are diagnosed by demonstrating in infected tissues or fluids or in stained histological sections broad hyphae that branch at 90° angles that usually lack cross-septations (Figure 8). The causative fungi can often be demonstrated in potassium hydroxide preparations of material from necrotic eschars in the nasopharynx or palate or from infected sinuses of people with rhinocerebral zygomycosis.

The various zygomycete genera and species are differentiated by morphologic features of fruiting and 'rootlet' structures that develop only in culture. However, it is sometimes very difficult to isolate these fungi in culture, even from specimens that are known to contain abundant hyphae by direct microscopy. Like *Aspergillus*, the fungi that cause zygomycosis cannot be isolated from the blood of infected people. There are no serologic tests for antibodies to the zygomycetes or immunoassays for zygomycete antigens.

Because zygomycosis tends to progress rapidly and is associated with high mortality rates, multiple therapeutic measures are generally required. First, every effort should be made to correct underlying host defense abnormalities such as diabetic ketoacidosis or uremic acidosis as quickly as possible. Similarly, immunosuppressive drugs should be stopped or their dosages reduced, if possible. Second, necrotic tissues should be surgically debrided and removed, even if extensive and disfiguring procedures are required. Next, antifungal therapy should be administered. Amphotericin B inhibits the growth of most of the zygomycetes and has been used with success in many patients with zygomycosis. The newer azole antifungal posaconazole has *in vitro* activity against many zygomycetes, whereas most other azoles do not, and at least one uncontrolled case series suggested that posaconazole may be effective in patients with zygomycosis who have not responded to or cannot tolerate amphotericin B.

Pneumocystis infections

Causative organism

Organisms in the genus *Pneumocystis* were once thought to be protozoans because of morphology and other characteristics, but genome sequence analysis has established that these are fungi in the phylum Ascomycota. *Pneumocystis* has been found in the lungs of many mammalian species, but it has not been cultivated *in vitro*. Thus, much of what is known about these fungi has been gleaned

Figure 8 *Rhizopus* and other zygomycetes grow as broad nonseptate hyphae that branch at angles of approximately 90°. Typical hyphae can often be demonstrated in potassium hydroxide preparations of infected tissues. (a) Zygomycete hyphae tend to invade within and along blood vessels, as in this section from the brain of a patient with fatal rhinocerebral disease (b).

from its morphology in infected hosts and from inferences from analyzing their genome sequences. Two morphologic forms are observed in infected lung tissues. Trophic forms are small (diameter 1–5 μm), uninucleate cells that appear to reproduce asexually by fission. Cystic forms are larger (diameter 5–10 μm) spherical structures with thick walls and as many as eight internal spores. As these structures resemble asci, they are presumed to develop as a consequence of mating between trophic cells of opposite mating type.

As different species of *Pneumocystis* appear to infect different mammalian species, the human pathogen that was once called *Pneumocystis carinii* (now the rat pathogen) is now called *P. jirovecii*. Environmental forms of *Pneumocystis* have not been described.

Epidemiology

Serologic surveys have shown that most healthy people develop antibodies to *P. jirovecii* during childhood. Animal studies indicate that *Pneumocystis* is acquired by inhalation, but it is not known if the infectious particles are spores or trophic cells acquired from infected individuals or if they are produced by an unknown environmental form of this fungus. Clinically apparent disease develops almost exclusively in people with cell-mediated immunodeficiency states associated with conditions such as advanced AIDS, neoplasia, malnutrition, or immunosuppressive drugs.

Pathogenesis and clinical features

The most common clinical manifestation of *Pneumocystis* infection is bilateral diffuse pneumonia. Most patients have fever, dry cough, and dyspnea. In some patients, the pneumonia can progress to severe disease and death over a few days; in others, the course is indolent over the course of several weeks. Histopathological examination of infected lung tissue generally reveals foamy eosinophilic exudates within affected alveoli. These exudates typically contain abundant *Pneumocystis* trophic cells and cysts. The host inflammatory response is usually mild. Extrapulmonary involvement of many different organs has been documented in patients with advanced AIDS, but is seldom of major importance.

Diagnosis and treatment

Pneumocystis pneumonia is usually diagnosed by demonstrating morphologically characteristic trophic cells and cysts in respiratory specimens or lung biopsies. Fluorescein-labeled monoclonal antibodies are available and are more sensitive for identifying *Pneumocystis* organisms than conventional staining methods. Immunoassays for *Pneumocystis* antigens in respiratory fluids and polymerase chain reaction tests for *Pneumocystis* DNA sequences have been developed, but these tests are not widely available.

The combination of a sulfonamide and trimethoprim is highly effective for the treatment of *Pneumocystis* pneumonia. Alternative therapeutic include pentamidine (either parenterally or by inhalation), atovaquone, dapsone plus trimethoprim, primaquine plus clindamycin, and trimetrexate. Adjunctive therapy with corticosteroids improves the outcome in AIDS patients with severe *Pneumocystis* pneumonia, presumably by attenuating host inflammatory responses to dead or dying fungi. Chemoprophylaxis against *Pneumocystis* pneumonia is effective in high-risk individuals who have not previously been infected (e.g., AIDS patients with low CD4+ lymphocyte counts, children with acute leukemia) and also in patients who have recovered from an initial episode. Effective chemoprophylactic agents include sulfamethoxazole/trimethoprim, dapsone, atovaquone, and pentamidine administered by inhalation.

Summary and Conclusion

The burden of disease caused by pathogenic fungi has increased markedly in recent decades, primarily because there are now many more people with significant deficiencies in host defenses against infections than there were as few as 20 years ago. Along with the recent increase in the frequency and importance of these diseases, our understanding of the basic biology of the pathogenic fungi and of their interactions with mammalian hosts has also expanded greatly. These advances have resulted in large measure from the sequencing of the genomes of several pathogenic fungi, the application of molecular genetic methods to fungal pathogenesis, and advances in understanding both innate and adoptive immune responses to infection by fungi and other pathogens. There have also been significant advances in recent decades in our ability to diagnose, prevent, and treat several serious fungal infections.

Defining Statement

The microflora of the human gastrointestinal tract has a profound influence on health and disease. The majority of the bacteria reside in the colon that they make up about one-half of the colon content and their total mass is 0.2 kg (Sender et al., 2016). The number of colon bacterial cells was most recently estimated as 3.8×10^{13} , the same order as that of human cells, which is 3.0×10^{13} . In 2014, an integrated human gut microbiome catalog of reference genes was established with 1267 sequenced metagenomics samples from 1070 people worldwide and it comprises 9,879,896 non-redundant genes (Li et al., 2014).

Problems Associated With the Study of Gastrointestinal Flora

The composition of the gastrointestinal (GI) microflora is complex and many different methodologies have been used to study it. Fecal matter is usually used as a proxy of gut microbiota. However, there is still no universally accepted protocol for fecal sample collection and the downstream analysis. Cultural studies were primarily used in the past but many of gut microorganisms are quite fastidious and are difficult (or impossible presently) to recover in culture, particularly if they are present in relatively small numbers. For cultural studies, a variety of media should be used, along with a variety of atmospheric conditions. Organisms vary greatly in their growth requirements. Unless selective and differential media are used, certain organisms present in lower counts may be overlooked. It is important to remember that many or most “aerobes” are actually facultative and therefore can grow on anaerobically incubated plate media. Selective media, while very useful, always lead to suppression of certain organisms. One of the principal problems of culture-based techniques is the fact that the majority of the indigenous flora of the GI tract cannot be detected. Most of these so-called “uncultivable” organisms (a better term for them would be “not yet cultured” organisms) are anaerobes or other very fastidious microorganisms. Molecular techniques provide the possibility to detect the majority of such organisms. Molecular studies using microbial DNA may also be inaccurate if the stool or other specimen is not thoroughly homogenized before the DNA is extracted. In studying mixed populations, there may be insufficient or preferential cell lysis, inhibition of PCR, differential amplification or formation of chimeric or artefactual PCR products.

In the past few years, sequencing technology have been vastly developed whereas the cost dropped dramatically. This makes next-generation sequencing (NGS) techniques become mainstreams in the study of GI flora. NGS is culture-independent and can produce huge amount of sequence data in a relatively short time. Being a complex microbial ecosystem, a human fecal sample usually has hundreds of members with complex interactions. NGS allows sequencing all members simultaneously, thus can better reflect the true microbial composition structure inside a sample. However, lack of reproducibility in GI flora investigations is common and still demands solutions. This problem is due to various known and unknown variations, which are from sample collection, storage, DNA extraction, sequencing strategies and data analysis (Thomas et al., 2015; Sinha et al., 2015; Costea et al., 2017).

Variation in GI flora among population is large since gut microbiota are influenced by many factors, for instance, diet, sex, age and health states of the host. In a Dutch population-based cohort with 1135 participants, 126 host factors investigated could account for 18.7% of the inter-individual variation in microbial composition. Of these 126 factors, which contained 31 host intrinsic factors, 12 diseases, 19 drug groups, 4 smoking categories, and 60 dietary factors, 110 in total were associated with 125 species (Zhernakova et al., 2016). Many clinical studies try to survey key microorganism or factors related to diseases by comparing several subject groups. A well designed study that can maximally minimize irrelevant variation is crucial for this purpose.

[☆]Change History: June 2019. M Zhang, J Wang, G Wu, H Li, L Zhao updated text and further readings to this entire article. Figure 1 and Table 1–8 were deleted.

This article is an update of S.M. Finegold, Gastrointestinal Microbiology in the Normal Host, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 422–443.

There is growing interest to define a healthy human gut microbiome. Large-scale projects, such as the Human Microbiome Project (HMP) and the Metagenomics of Human Intestinal Tract (MetHIT), have sequenced microorganisms from normal humans and generated a microbiome baseline catalog. Besides phylogenetic and taxonomic information, host biogeography, ecology, metabolism, and function are also included (Human Microbiome Project Consortium, 2012b; Qin et al., 2010). However, the definition of “healthy” or “normal” gut microbiome is still under controversy. Large degree of diversity among individuals even in the population without apparent disease is one of the major reasons. There may be a certain common “core microbiota,” which in healthy adults appears to be dominated by Firmicutes and Bacteroidetes, followed by Actinobacteria, Proteobacteria, and Verrucomicrobia (Hollister et al., 2014). Some researchers have attempted to discover a species-level core in healthy adults, which including *Faecalibacterium prausnitzii*, *Roseburia intestinalis*, and *Bacteroides uniformis* (Qin et al., 2010). Unfortunately, the total abundance of these species was less than 0.5% in some other individuals (Turnbaugh et al., 2009). Given the complexity and diversity of gut microbiota in healthy adults, it may be difficult to define a “core microbiome” set at the species-level. An alternative conceptualization, “functional core microbiome” set is proposed in healthy individuals, collecting functional genes and pathways rather than species or genera (Nicholson et al., 2012; Zhang et al., 2015a,b). This is because healthy individuals, even with varied gut microbiota structure, all contain pathways for central carbohydrate and amino-acid metabolism. Some functions are variable among the population, such as vitamin and drug catabolism, pathogenicity islands, motility and nutrient transporters (Bäckhed et al., 2012; Lozupone et al., 2012). In 2011, based on unconstrained canonical correspondence analysis of the genus-level compositional profiles, the term “enterotypes” was proposed. Individuals were classified into three groups (enterotypes) according to the abundance pattern of three taxa *Bacteroides*, *Prevotella*, and *Ruminococcaceae*, which had largest variation among the population (Arumugam et al., 2011). The obtained three enterotypes appeared to be independent of BMI, age, gender or nationality, but were correlated with diet. Individuals on an animal-based diet had been proved to have a *Bacteroides* dominated enterotype, whereas those on plant-based diet have a *Prevotella* dominated one (Wu et al., 2011). However, debates on calculation that result in “enterotypes” still continue (Knights et al., 2014; Gorvitovskaia et al., 2016). Further research is necessary to determine whether discrete enterotypes or fluid “enterogradients” is a better to describe the human microbiota composition, and to reveal the further biological significance under enterotypes (Bäckhed et al., 2012; Costea et al., 2018).

Techniques for Study of Gastrointestinal Flora

There are many protocols for cultural studies of GI flora. It is important that good anaerobic conditions are provided during transport of the specimens and for the culture and examination processes. With GI flora, many organisms are quite fastidious and may not survive if they are cultured in an anaerobic jar and then removed to an aerobic atmosphere while the plates are examined before sub-culturing.

Various molecular approaches may be used and will provide a remarkable amount of additional information. Clone libraries, while tedious and time-consuming, have been used with excellent results. Terminal restriction fragment length polymorphism (T-RFLP) has been considered to be promising for analysis of communities such as GI flora but is somewhat lacking in precision. Denaturing and temperature gradient gel electrophoresis (DGGE and TGGE) and fluorescent in situ hybridization (FISH) have also been used effectively for community flora analyses. Probe grids or DNA checkerboard hybridization may be used and DNA microarrays are available, but not with a comprehensive array for GI flora. A preferred technique is real-time PCR. It requires that one have primer-probes for target sequences of groups of organisms or for each individual organism that may be present (which immediately places limitations since we do not yet know the total makeup of GI microflora communities). For studies of known organisms for which there are primer-probes high-throughput methods, such as pyrosequencing techniques provide quantitation as well as accurate identification, and detection of organisms that are present in small numbers.

NGS technologies have revolutionized the studies of GI flora through a culture-independent, relatively high precision and high-throughput strategy to explore the microbial community in a complex ecosystem. The fast-evolving sequencing platforms include 454 pyrosequencing, Illumina, Ion Torrent and PacBio etc. Measurements of microbiota may be based on 16S rRNA and other marker genes. In addition of sequencing the near-full-length clones, much higher throughput methods are generally performed to sequence the PCR amplicons of targeted hyper-variable regions of 16S rRNA genes. Assigning such 16S rRNA gene amplicon sequences into operational taxonomic units (OTU) based on the similarity thresholds becomes a basic protocol in microbial community studies. The similarity thresholds of sequences can vary to represent different levels of taxonomic composition, e.g., 97% similarity stands for species and 95% similarity for genera (Goodrich et al., 2014). Several pipelines such as QIIME (Caporaso et al., 2012), mothur (Schloss et al., 2009), and UPPARSE (Edgar, 2013) have been developed to combine the quality filtration, chimera detection, OTU picking, taxonomy classification and downstream analyses altogether. Other efforts have also been introduced to bypass the similarity threshold based OTU picking strategy to achieve more detailed resolution (Tikhonov et al., 2015; Shokralla et al., 2015; Burke and Darling, 2014). More recent methods include Swarm, DADA2 and Deblur. Swarm clusters OTUs by connecting nearly identical sequences (Mahe et al., 2015). DADA2 and Deblur provide denoised error-free sequences for the inference of single nucleotide differences-amplicon sequence variants (ASVs) (Callahan et al., 2016; Amir et al., 2017).

Whole metagenomics, which target on the whole DNA of the microbiota in the GI flora, are used to provide both structural and functional information. The first human gut microbial gene catalog (~3.3 million genes) was established in 2010 (Qin et al., 2010) and the integrated catalog of reference genes (~9.9 million genes) in the human gut microbiome was published in 2014 (Li et al., 2014).

Information from >1800 independent human gastrointestinal metagenomic samples had been included in Human Pan-Microbe Communities Database (HPMCD) since 2015 and could provide standardized phylogenetic classification at species level (Forster et al., 2016). High-quality microbial genomes can be assembled from metagenomics directly with the emerging methods (Nielsen et al., 2014; Kang et al., 2015; Sangwan et al., 2016). For instance, Parks et al. reconstructed ~8000 bacterial and archaeal genomes from >1500 metagenomic datasets, which increased phylogenetic diversity and expanded our understanding of the tree of life (Parks et al., 2017). In addition, metatranscriptomics, which identifies RNA-based regulation and expression level in ecosystem, and metaproteomics, which is for large-scale characterization of the whole protein in the microbial community, have been applied in the study of GI flora. For instance, by combining the metatranscriptome and metagenome of the human gut, Franzosa et al. found the subject-specific whole-community regulation (Franzosa et al., 2014). In a review about human gut microbiome metaproteomics, Xiong et al. listed considerations for metaproteome measurement and subsequent information analysis (Xiong et al., 2015). They also highlighted the distinctness and complement of functional information between metaproteome and metagenome. Cheng et al. recently developed MetaLab, an integrated software platform for metaproteomic analysis, to facilitate microbiome studies (Cheng et al., 2017).

Normal Flora of Esophagus

It has generally been considered that the esophagus has no resident microflora that bacteria occur there only transiently and represent swallowed organisms from the oral cavity. However, a paper in 1983, using older techniques, did find aerobic organisms in all subjects studied and anaerobes in 80% of subjects. The most common aerobes might have represented oral flora—*Haemophilus*, *Neisseria*, and streptococci and yeasts, but coliforms were found in half the subjects. The most common anaerobes encountered were anaerobic cocci and *Bacteroides*, including *Bacteroides fragilis*. Recently, diverse techniques have been used to reveal the resident bacteria in the esophagus. A study based on 16S rDNA clone libraries of esophageal microbiota was performed on four persons and detected up to 6 phyla and 41 genera, among which *Streptococcus*, *Prevotella*, and *Veillonella* were prevalent (Pei et al., 2004). The cultivation based bacteria identification of both brush and biopsy samples in a cohort of 40 persons also validated that the esophageal bacterial community is predominated by viridans streptococci and fusiform rods, then *Neisseria*, *Haemophilus*, and *Prevotella* species. The similarity of oral and esophageal microbiota suggested that oral is the source of bacterial seeds transported to esophagus. The biopsy samples indicated that the bacteria are not just transient passing the surface but also residing in the epithelia, especially for Streptococci that have a strong capacity to adhere to mucosal linings (Norder Grusell et al., 2013). Further studies also revealed the correlation between the alteration of esophageal microbiome and the risk of gastroesophageal reflux disease, Barrett's esophagus, esophageal adenocarcinoma, esophageal squamous cell carcinoma, and eosinophilic esophagitis (Snider et al., 2016; May and Abrams, 2018). To satisfy the increasing requirements of sampling esophageal microbiota, a novel device using minimally invasive technology also been made to perform "Esophageal String Test" to accelerate the study of esophageal microbiome (Fillon et al., 2012).

Normal Flora of Stomach

Stomach is an interesting and unique niche for bacteria. Many bacteria enter the stomach through oral cavity and refluxing from the duodenum, but most of them are killed by the low pH of the stomach. For a long time, gastric mucosa was considered sterile. The discovery of *Helicobacter pylori* in 1983 changed this view and more bacteria have been identified in stomach due to the application of cultural independent technology. Bik et al. analyzed gastric mucosa of 23 healthy adults and found 128 phylotypes, of which most belonged to the Proteobacteria, Firmicutes, Actinobacteria, Bacteroidetes, and Fusobacteria phyla (Bik et al., 2006). Based on cloning and 16S rRNA sequencing, Li et al. identified that 99.0% of gastric microbiota sequences from five healthy subjects belonged to five phyla (Firmicutes, Bacteroidetes, Actinobacteria, Fusobacteria, and Proteobacteria) (Li et al., 2009). Engstrand et al. analyzed the gastric microbiota of 13 healthy subjects and identified similar results as mentioned before even though the DNA extraction methods, primer design and sequencing were different in each study (Engstrand and Lindberg, 2013). Delgado et al. investigated the microbiota of stomach mucosa biopsies and gastric juices from 12 healthy persons. They combined culture and culture-independent techniques and found four main genera: *Propionibacterium*, *Lactobacillus*, *Streptococcus*, and *Staphylococcus* (Delgado et al., 2013). The results of these studies based on the different populations were consistent with each other even though the large degree of inter-individual variability existed. The composition of gastric microbiota is dynamic. Researchers have identified several factors including diet, antibiotic medication, inflammation of gastric mucosa, pH and *H. pylori* colonization can affect it (Nardone and Compare, 2015).

Normal Flora of Small Intestine

The small intestine has three major regions: duodenum, jejunum and ileum. It is the main place where most nutrients are digested and absorbed. The small intestine is a relative harsh environment for microorganism due to the short transit time and the presence of digestive enzymes, bile, oxygen and pH limits, and there is a significant distinction exists in microbiota between the small

intestine and colon (Zoetendal et al., 2012; Donaldson et al., 2016). The knowledge of the microbial composition and metabolic pathways that are operating in the small intestine microbiota is limited due to poor physical accessibility. Some studies exploited a flexible silicone sampling probe, which was introduced by individual mouth until it reached the small intestine, being monitored by radioscopy (Zilberstein et al., 2007).

The small intestine exhibits lower bacterial diversity than the colon, and the microbiota composition varies between different locations in the intestine tract (Zoetendal et al., 2012, Donaldson et al., 2016). The five major phyla present in duodenal microbiome are Proteobacteria, Actinobacteria, Bacteroidetes, Firmicutes, and Fusobacteria, and the dominant genera are *Streptococcus*, *Acinetobacter*, *Propionibacterium*, *Prevotella*, *Bacteroides*, *Neisseria*, *Haemophilus*, *Fusobacterium*, *Actinobacillus*, and *Porphyromonas* (Li et al., 2015, D'Argenio et al., 2016). The mainly enriched microorganisms in the jejunum are *Veillonella*, *Bacteroides*, *Clostridium*, *Proteus*, *Staphylococcus*, *Escherichia coli*, and *Klebsiella* (Zilberstein et al., 2007; Sullivan et al., 2003). Due to varied physiological environments, such as pH, phosphate buffer and bile salts, the floras in the upper ileum are similar to those of the jejunum. The upper ileum is enriched with *Veillonella*, *Bacteroides*, *Staphylococcus*, *Enterobacter*, *Corynebacterium*, *Escherichia coli*, and *Peptococcus*. Whereas in the distal ileum, the dominant microorganisms are *Veillonella*, *klebsiella*, *Clostridium*, *Corynebacterium*, *Propionibacterium*, *Escherichia coli*, and *Bacteroides* (Quintanilha et al., 2007; Zilberstein et al., 2007).

Normal Flora of Colon

Succession of Flora in Infants

The GI tract is sterile at birth and the colonization of GI microbiota undergoes dramatic changes in composition during the first year of life. Facultative aerobes (*Enterobacteriaceae*, *Enterococcus*, and *Streptococcus*) first colonize the neonatal gut at birth due to the presence of abundant oxygen in the gut, but once the oxygen is used up by these facultative aerobes, obligate anaerobic genera (*Bifidobacterium*, *Bacteroides* and *Clostridium*, etc.) take the place and predominate in the suckling period (Vael and Desager, 2009). The composition of gut microbes is less complex but more dissimilar among newborns (Backhed et al., 2015). During the weaning process, supplying solid foods causes a significant shift in the infant gut micro-ecology (Fanaro and Vigi, 2008), and finally a gut microbiota broadly similar to that of adults is established by the age of 1 year (Palmer et al., 2007).

Delivery mode, feeding type and mothers' gut microbiota affect the composition of the newborns' gut microbiota. Compared to babies delivered by C-section who receive the skin, mouth and environmental bacteria randomly as the seeds for their gut microbiota, the babies delivered vaginally get the first inoculum for their gut microbiota from the bacteria present in the birth canal of the mothers, so babies delivered naturally develop healthier gut microbiota with important microbes such as *Bacteroides* and *Bifidobacterium* (Backhed et al., 2015; Dominguez-Bello et al., 2010).

Breast milk is an ideal source for the babies' commensal microbiota and continuous promoter for beneficial gut bacteria since it contains both probiotics derived from the mothers' intestine and prebiotic oligosaccharides that promote the growth of beneficial probiotics (e.g., *Bifidobacterium*) (Martin et al., 2003, 2012; Coppa et al., 2006). The gut microbiota of breast-fed infants is dominated by *Bifidobacterium*, which is considered protective for infant health (Rivero-Urgell and Santamaria-Orleans, 2001). In contrast, the gut of formula-fed infants, who have a higher incidence of infections, is colonized by an adult-type gut microflora in which *Bacteroides*, *Clostridium*, *Bifidobacterium*, *Lactobacillus*, Gram-positive cocci, coliforms, and other groups are all predominantly represented (Gad, 2007). The weaning process is the major driving force of the succession of gut microbiota in infants, resulting in the enrichment of *Roseburia*, *Clostridium*, *Anaerostipes* etc. However, such compositional and functional shift of gut microbiota does not happen even though solid food has been introduced to infants, until the breast-feeding is entirely stopped. The breast-feeding has been shown to be associated with the adult microbiota community type and may influence the life-long profiles of metabolic and immune systems (Ding and Schloss, 2014).

The gut microbiota established in first years of life plays a fundamental role in the host health not only in infancy but also in childhood and adulthood by affecting the digestion and nutrition, modulating the maturation of the immune system, resisting pathogens, influencing the energy storage and obesity, and even affecting the behavior of host through the metabolism of vitamins, iron, and amino acids that are essential for the development of neuro and brain (Vael and Desager, 2009; Fanaro and Vigi, 2008; Hsiao et al., 2013; Diaz Heijtz et al., 2011).

Cultural Studies of the Microflora of the Adult Colon

Cultivation of GI flora is time-consuming and laborious. Nevertheless, it is an indispensable procedure for providing detailed physiological and functional features of individual microorganisms. Rajilic-Stojanovic and de Vos systematically reviewed 1057 microbial species that can reside in the human gastrointestinal tract and have been identified, which consist of 92 *Eukarya*, 8 *Archaea*, and 957 *Bacteria* (Rajilic-Stojanovic and de Vos, 2014). More the remaining GI flora are expected to be cultured in the future.

Molecular Studies of the Microflora of the Colon

The rapid improvement of high-throughput sequencing technology greatly facilitates the molecular studies of colonic flora as a complex ecosystem. The composition of human gut microbiota encompasses over 1000 species (Hollister et al., 2014) and is

immensely variate between individuals and dynamic at different ages (Lozupone et al., 2012), though it is deemed to be essentially stable throughout adulthood (Nicholson et al., 2012). Host factors, including genetics, immune system, age, diet and drug administration, appear to affect the human gut microbiota in the normal state (Tuddenham and Sears, 2015). Dysbiosis of gut microbiota has been proved to be associated with many diseases, such as obesity, malnutrition, inflammatory bowel disease, neurological disorders and cancer (Dicksved et al., 2008; Fei and Zhao, 2013; Kau et al., 2011; Ley et al., 2006; Lupton, 2004).

The international initiatives of human microbiome research, like MetaHIT and HMP, have greatly accelerated the studies on gut microbiota. Financed by the European Commission under the 7th FP program, the main objective of MetaHIT is to study associations between the human intestinal microbiota and human health, in particular two diseases, inflammatory bowel disease and obesity (<http://www.metahit.eu>). MetaHIT had sequenced fecal samples of 124 Europeans using Illumina-based metagenomic sequencing platform and obtained 3.3 million non-redundant microbial genes from 576.7 gigabases of sequences. About 1000–1150 prevalent bacterial species in total were estimated and each individual harbors at least 160 species (Qin et al., 2010). Two phyla, Bacteroidetes and Firmicutes had the highest abundance.

Funded by the National Institutes of Health, HMP Consortium has established a framework to develop metagenomic protocols and to generate high-throughput metagenomic data. With 242 healthy adults, each sampled at 15 or 18 body sites up to three times, 5177 microbial taxonomic profiles from 16S ribosomal RNA genes and over 3.5 terabases of metagenomic sequence were obtained. About 800 reference strains isolated from the human body have been sequenced (Consortium, 2012b). Similar to the result from MetaHIT, the dominant phyla in the gut are Bacteroidetes and Firmicutes (Consortium, 2012a). In 2017, Lloyd-Price et al. reported an expanded dataset from 265 individuals of the HMP cohort, which contained 1631 new whole-metagenome sequencing samples at multiple time points (Lloyd-Price et al., 2017).

A deep 16S rRNA sequencing survey of fecal microbiota was conducted in China, which covered 314 healthy young adults from 7 ethnic groups living in 20 rural or urban regions of 9 provinces. The four most dominant bacterial phyla in this population were Firmicutes (73.47%), Bacteroidetes (14.13%), Proteobacteria (5.83%), and Actinobacteria (3.36%). In Archaea, Euryarchaeota (2.62%) was the only detected phylum (Zhang et al., 2015b). Inconsistent with previous study, *Phascolarctobacterium* was the most predominant genus, instead of *Bacteroides* (Arumugam et al., 2011) and *Faecalibacterium* (Nam et al., 2011). Among the 279 identified genera, nearly half of the total sequences were from nine predominant genera, *Phascolarctobacterium*, *Roseburia*, *Bacteroides*, *Blautia*, *Faecalibacterium*, *Clostridium*, *Subdoligranulum*, *Ruminococcus*, and *Coprococcus*. These genera co-existed in all samples and all of them are short-chain fatty acid producers. The cluster of 314 microbiota samples was mainly relevant to host's ethnicities/geography and less to lifestyles. The ratios of Firmicutes: Bacteroidetes among the individuals varied from 0.5 to 300.6.

Falony et al. investigated variation of fecal microbiome in two independent healthy populations: the Belgian Flemish Gut Flora Project with 1106 subjects and the Dutch LifeLines-DEEP study with 1135 subjects. They found medication had the largest effect size on the variability of fecal samples while influence from early-life events such as birth mode was minor (Falony et al., 2016). When the two datasets integrated with other U.K. and U.S. studies, 664 genera from 3948 subjects were identified. They further found a core microbiota containing 14 genera, including *Veillonellaceae*, *Ruminococcaceae*, *Lachnospiraceae*, *Hyphomicrobiaceae*, *Erysipelotrichaceae*, *Clostridiales*, *Clostridiaceae*, *Roseburia*, *Faecalibacterium*, *Dorea*, *Coprococcus*, *Clostridium_XIVa*, *Blautia*, and *Bacteroides*. Through simulation, they estimated that the genera richness of total western gut microbiota was 784 and they need additional 40,739 individuals obtain the rest genera.

Studies of Individual or Special Groups

A recent clinical dietary intervention on 17 Prader-Willi syndrome and 21 simple obesity children showed that a diet rich in non-digestible carbohydrates could significantly reduce body weight, decrease serum antigen load and alleviated inflammation (Zhang et al., 2015a). Shifts of gut microbiota were observed after the intervention. Through 161 assembled bacterial draft genomes, increased functional genome groups were detected. These groups can produce acetate from carbohydrates fermentation. Meanwhile, trimethylamine N-oxide and indoxyl sulfate, detrimental host-bacteria co-metabolites, were significantly decreased in the urine after the intervention. These co-metabolites were correlated with some bacterial genomes, which encode enzyme genes for production of the co-metabolite precursors by fermentation of choline or tryptophan in the gut. Both pre- and post-intervention gut microbiota from a volunteer were transplanted into two groups of germ-free mice, respectively. Higher inflammation level and larger adipocytes were occurred in the pre-intervention group. Furthermore, Wu et al. found that the dietary intervention also significantly reduced the richness and diversity of the gut resistome of the obese children, and especially reduced bacteria with multi-resistance potential (Wu et al., 2016). The concept "resistome" was introduced by D'Costa et al. in 2006, which refers to the collections of the enteric antibiotic resistance genes (ARGs). The human gut microbiota is a reservoir for ARGs. ARGs can appear in the gut microbiota in the early age of human beings. Even in the fecal samples of healthy infants and children, diverse and novel ARGs have been identified. As antibiotic resistance has been one of the greatest global threats to human health, there is considerable need to characterize the resistome of the human gut microbiota and to understand its diversity and richness, and the spreading mechanisms between different members, especially between commensals and opportunistic pathogens. A total of 1093 ARGs of gut microbiota were found from 162 individuals from China, Denmark and Spain. The Chinese individuals harbored the highest number of ARGs while the resistomes of the two European populations were more closely related (Hu et al., 2013). Forslund et al. found ARGs for 68 classes and subclasses of antibiotic in 252 fecal samples, at an average of 21 ARGs per sample (Forslund et al., 2013). They further derived and compared the resistomes of human gut microbes from 832 individuals located in 10 different countries. Significant differences were detected between samples and were associated with antibiotic usage and exposure in medical and food production

context (Forslund et al., 2014). Feng et al. compared the resistomes in fecal samples from 180 healthy individuals from 11 different countries and found 7 common multidrug ABC transporters in all individuals. In addition, via occurrence networks between ARGs and microbial taxa, they identified potential hosts for 58 ARG subtypes (Feng et al., 2018).

Addendum

GI microbiota affect human healthy and are also being influenced by various factors from host and environment, forming a complicated ecosystem. Many gastrointestinal and metabolic diseases have been associated with the dysbiosis of the GI microbiota. A large number of epidemiologic investigation and clinical intervention have provided helpful information in understanding the features of functional microbiota, which could be served as drug/diet targeted candidates in treating diseases associated with disrupted microbiota. For instance, Zhao et al. recently found that a diet rich in diverse fibers could selectively increase a group of short chain fatty acid producing gut bacteria and this promotion was associated with the alleviation of type 2 diabetes (Zhao et al., 2018). Such work provided promising solution to manage metabolic disease through gut microbiome targeted nutrition intervention. The application of emerging multi-omics technologies combined with statistical and bioinformatic tools facilitates the identification and elucidation of potential key microorganisms to human health. Advances in genomic techniques assisted with bioinformatics allow dissection of those microorganisms at strain-level. Though demonstration of causality is still not easy, functional strain candidates can be validated through gnotobiotic models.

Gene Transfer Agents

Introduction

Gene transfer agents (GTAs) are small bacteriophage-like particles produced by some bacteria and archaea (see Fig. 1). Each GTA particle contains a short fragment of cellular genomic DNA that it can inject into a closely related recipient cell. The transferred DNA can then recombine with the recipient's genome, possibly changing its genotype in a process similar to transduction. GTAs are typically encoded by bacteriophage-derived genes in the producing cell's chromosome, with the genes encoding the particle head and tail usually in a single operon or cluster; genes for other functions (regulation, cell lysis, etc.) may be dispersed at other locations. In the well-studied GTA systems the expression of GTA genes has been found to be under control of cellular regulatory systems. GTA genes have complex evolutionary histories and the evolutionary forces responsible for their maintenance are not yet well understood.

GTA particles resemble small DNA phages, but the relationship between GTAs and phages is complex. Phages and prophages are even more ubiquitous than bacteria, and their genes frequently recombine with each other. Since phage and bacteria have been coevolving for billions of years, and because of the coexistence within cells of the phage and host genomes, their intertwined histories can make it difficult to distinguish between phage and host genes.

Many phages are temperate and integrate their DNA into a host chromosome, where it may remain repressed as a prophage for many generations. Most bacterial genomes contain multiple prophage sequences; some of these appear intact and functional, but others are obviously defective, having undergone various forms of mutational and deletional degeneration. Several of the known GTAs are produced by sets of phage structural genes that have come under the control of cellular regulation machinery.

Phages evolve as infectious agents; introduction of phage DNA into a host cell leads to expression of phage genes and release of particles containing phage DNA, which can go on to infect new cells. In contrast, GTA particles are not infectious because they are typically too small to contain the gene clusters encoding them. However, both phage and GTAs can mediate gene transfer (Fig. 1 (A)). Phage particles normally contain only phage DNA, but occasionally a particle will package a fragment of host DNA instead, and when the particle injects this DNA into another cell the DNA can recombine with the chromosome and change its genotype. This process is called transduction. Although transduction by phage appears to be an unselected consequence of accidental packaging errors, transduction-like gene transfer appears to be the primary function of GTAs because they consistently package chromosomal DNA, with no preference for GTA genes (Fig. 1(B)).

Fig. 1 Similarities and differences between typical DNA phage infection and induction of GTA. (A) Phage infection and transduction. (B) GTA production and gene transfer.

Fig. 2 Discovery and detection of GTAs. (A) Marrs' first experiment. Step 1, cultures with different antibiotic-resistance marker genes were mixed. Step 2, the mixed culture was grown for several generations. Step 3, recombinants were detected by plating on agar containing both antibiotics. (B) General assay for GTA-mediated gene transfer. Step 1, a culture of genetically marked donor cells (e.g., Rif^R) is filtered to remove the cells and treated with DNase to remove free DNA. Step 2, the filtrate is mixed with unmarked recipient cells. Step 3, the recipient cells are plated on selective agar to detect recombinants.

Table 1 Properties of different GTAs

GTA, producing organism(s)	Size of DNA (kb)	Morphology type	Production in related organisms
RcGTA, <i>Rhodobacter capsulatus</i>	4	Siphovirus	Yes
Dd1, <i>Desulfovibrio desulfuricans</i>	13.6	Podovirus	Not known
VSH-1, <i>Brachyspira hyodysenteriae</i>	7.5	Siphovirus	Unlikely
VTA, <i>Methanococcus voltae</i>	4.4	Siphovirus	Not known
BaGTA, <i>Bartonella henselae</i>	14	Non-tailed or podovirus	Yes

Discovery of GTAs

The first GTA was discovered in 1974 by Barry Marrs, using a coculture experiment designed to detect *Rhodobacter capsulatus* (then *Rhodopseudomonas capsulata*) recombinants arising by conjugation, transduction or transformation (see Fig. 2). Mixtures of some strains yielded many recombinant colonies, and the responsible process could not have been conjugation, because the transfer property remained in the culture medium after the cells were removed by filtration. Natural transformation by free DNA in the filtrate was also ruled out, because adding DNase to the filtrate did not reduce its activity. However, the process also differed from transduction, since inactivation assays suggested that the particles were small, and there were no signs of the cell lysis expected of a phage-mediated process. The entity responsible for genetic recombination was named the "Gene Transfer Agent".

This discovery was followed by electron microscopy analysis showing that the *R. capsulatus* GTA particles physically resemble unusually small tailed phages, and extraction of DNA from these particles, showing that they contain apparently random 4–5 kb segments of chromosomal DNA. Approximately 20 years then elapsed before the responsible genes were identified in the *R. capsulatus* chromosome, regulation by host proteins was characterized, and subsequently GTA-producing cells were shown to release their GTA particles by lysis.

Meanwhile, functionally similar GTAs were being discovered in other systems (Table 1), and to prevent confusion the *R. capsulatus* GTA was renamed RcGTA. As described in more detail below, RcGTA relatives are widespread in a large clade of the alpha-proteobacteria. A small subclade of these bacteria, the *Bartonella* species, contain an independently derived GTA (BaGTA). GTAs are now also known in the delta-proteobacterium *Desulfovibrio* (Dd1), in the spirochaete *Brachyspira* (VSH-1) and in the euryarchaeote *Methanococcus* (VTA).

Fig. 3 Regulation of RcGTA production and recipient capability. Step 1, quorum-sensing and phosphorelay signals induce expression of GTA genes. Step 2, an uncharacterized stochastic process limits expression of the GTA cluster and lysis genes to a small fraction of the population. Steps 3 and 4 (only in the GTA-producer subpopulation), the GTA cluster is expressed and other genes needed for GTA production are expressed (lysis, head-spike and attachment functions) Step 5 (in the non-producer subpopulation), genes for capsule production and for DNA processing are expressed.

GTA Genes and Regulation

The GTA major head and tail proteins are typically encoded by a cluster of co-transcribed genes. Other proteins needed for GTA production (head spikes, tail fibers, lysis proteins) and DNA uptake (receptors and DNA-transport proteins) may be encoded elsewhere in the genome. Several GTA systems that have been investigated are regulated by cellular factors. Fig. 3 shows the regulatory processes for RcGTA, the best-studied system, which control both RcGTA production and the ability to be a recipient of genes carried by an RcGTA particle. In the best-studied systems, *R. capsulatus* and *Bartonella henselae*, regulation of GTA gene expression is under direct control of specific cellular regulators, with an uncharacterized stochastic process determining which cells will participate in production of particles.

In *R. capsulatus*, the activity of a cellular phosphorelay pathway culminating in the response regulator CtrA appears to differentially activate RcGTA structural genes early after the start of induction and, later in the inductive process, other genes needed for maturation and lytic release. This is analogous to early and late gene expression in the induction of prophages such as λ , but involves cellular genes instead of phage or phage-homologous genes. The production and release of RcGTA particles is activated in only a small subset of the population (<3%). Furthermore, the same regulatory processes (quorum sensing, the CtrA phosphorelay) act in the non-producing fraction of the population, enhancing the ability to bind RcGTA particles and import RcGTA-borne DNA. This recipient capability depends on the production of an extracellular polysaccharide that binds RcGTA particles, on proteins needed to translocate inserted DNA from the periplasm to the cytoplasm, and on the cytoplasmic DprA protein that, with RecA, promotes integration of DNA into the genome; all of these are induced by CtrA and quorum sensing. The related DsGTA, produced by *Dinoroseobacter shibae*, is also regulated by quorum sensing and the CtrA phosphorelay.

The above regulatory processes lead to maximal RcGTA production in post-growth cultures, but the *Bartonella* GTA BaGTA is maximally induced during exponential growth, with the ppGpp-dependent stringent response preventing expression at other times. In this system, the BaGTA genes are induced in approximately 6% of the population. The uptake of DNA from BaGTA particles is dependent upon cell division proteins, meaning that only actively dividing cells are able to act as recipients.

The *Brachyspira* GTA VSH-1 differs from other GTAs, and resembles many prophages, in being induced by DNA-damaging chemicals such as mitomycin C and peroxide. This could reflect control by a phage-derived damage-responsive repressor like the phage λ cI protein or regulation by a cellular SOS system. VSH-1 also differs from other GTAs in being induced throughout the cell population rather than in only a small subset of cells.

Fig. 4 Production of GTAs. (1) The genes encoding GTA structural components and necessary functions are transcribed. (2) Head and tail proteins are assembled into empty heads and detached tails. (3) Heads are filled with chromosomal DNA and tails are attached. (4) Holin and endolysin proteins cause cell lysis, releasing the particles.

GTA Production

Induction of GTA genes leads to production of GTA proteins but not to specific replication of the GTA-encoding DNA (see Fig. 4). The strong degree of sequence identity between phage and GTA proteins suggests that, as in phages, GTA head particles are initially assembled as empty shells that are then filled with uniform-length DNA segments by a terminase enzyme complex before the tail is attached to the head. Fragment lengths differ between systems from approximately 4 to 14 kb (Table 1) and this is thought to reflect 'headful' packaging rather than use of a specific packaging-recognition sequence like the λ *cos* sequence. Phage-homologous lysis proteins (holin and endolysin) then lyse the cell to release the GTA particles.

Lack of Specificity of DNA Packaging

Unlike phage, GTA particles do not preferentially package the DNA that encodes them. In RcGTA and BaGTA the DNA fragments are randomly derived from all of the DNA available in the cell (GTA-encoding genes are not preferentially packaged), although local DNA over-replication may enrich this DNA for certain regions. For RcGTA, analysis of DNA extracted from GTA particles shows even representation ($\pm 25\%$) across the *R. capsulatus* genome. A sharp dip in coverage at the site of the GTA gene cluster suggests that DNA packaging may be inhibited by the intense transcription of these genes in GTA-producing cells. In BaGTA particles, one region of the *Bartonella* genome is overrepresented about tenfold; this is not due to biased packaging but to over-replication, thought to be centered at an active phage-derived origin of DNA replication not associated with the BaGTA gene cluster.

A very different picture is seen for chromosomal DNA coverage in the GTA produced by *D. shibae*, with very distinct peaks and valleys not explained by differences in cellular DNA abundance. Different replicons within the *D. shibae* cells are also packaged at different frequencies, with the chromosome and chromosome-like plasmids packaged significantly more than the small plasmids. No clear correlation with GC-content or specific packaging motifs is seen, suggesting that differences in the DNA's physical properties may affect the initiation of packaging. The mechanism(s) underlying these biases is(are) currently unknown. As with RcGTA, the GTA genes are underrepresented in particles, again perhaps due to transcriptional interference with packaging.

Fig. 5 GTA-mediated gene transfer. Step 1, GTAs attach to cell-surface polysaccharide capsule (outer layer shown in orange) and inject their DNA across the outer membrane. Step 2, competence-associated proteins transport one strand across the inner membrane. Step 3, non-homologous DNA is degraded. Step 4, homologous DNA replaces one chromosomal DNA strand by RecA-mediated recombination.

GTA DNA Injection and Recombination

Whether the GTA particles released by a cell go on to transduce other cells depends on their ability to survive in the environment and on the presence of suitably prepared recipients. Nothing is known about environmental effects on GTA survival, although the discoverers of RcGTA did report that the gene transfer properties of their GTA preparations were much less stable than similar phage lysates. The regulation of RcGTA production by quorum sensing presumably serves to ensure the availability of a dense population of closely related recipients.

As mentioned above, RcGTA attachment depends on the presence of a cell surface capsular polysaccharide (see Fig. 5). The next step, DNA injection, differs from that of phages because the RcGTA-packaged DNA is not injected directly into the cytoplasm. Instead the DNA is inserted into the periplasmic space between the inner and outer membranes. Movement of the DNA from the periplasm to the cytoplasm requires cellular homologs of the DNA-translocation proteins ComEC, ComF and ComM, previously known only for their roles in natural transformation by competent cells. In competent cells, and presumably in RcGTA recipients, these proteins transfer only a single strand of the initially double-stranded DNA across the inner membrane and coat it with the recombination-promoting DprA protein. Once in the cytoplasm recombination is thought to occur by the same RecA-dependent steps as in natural transformation, because the proteins DprA and RecA are essential.

Evolutionary History of GTAs

Prophage-derived gene clusters that might be GTAs are widespread in bacteria and archaea, often annotated as defective prophages. At present there is no good way to decide which of these might be genuinely functional GTAs and these organisms would need to be tested for high-frequency gene transfer, as illustrated in Fig. 1, or for production of small phage-like particles containing random segments of chromosomal DNA. In principle, sequence-based criteria could be developed for GTA genes, but these would need to be validated by experimental demonstration of GTA production.

Although the different GTAs are encoded by phage-derived genes with similar functions, they appear to have originated independently. The three genetically defined GTAs, RcGTA, VSH-1 and BaGTA, are not directly evolutionarily related. Furthermore, there are no obvious homologs of these GTAs' genes in the genomes of *Desulfovibrio desulfuricans* or *Methanococcus voltae*, indicating the GTAs produced by those organisms also have independent evolutionary origins.

The first step in the transition from prophage to GTA could be a simple deletion or rearrangement that replaces the left half of the prophage with a chromosomal promoter (Fig. 6). This would need to be followed by mutational changes to the terminase to facilitate packaging of all chromosomal regions and to the capsid to produce smaller heads relative to genuine phages. Genes for cell lysis appear to have undergone subsequent rearrangement and replacement events in *R. capsulatus*.

In addition to having different evolutionary origins, the different GTAs appear to have very different evolutionary histories within their organisms' chromosomes. Homologs of genes encoding VSH-1, the *B. hyodysenteriae* GTA, are present in the genomes of other species within the genus *Brachyspira*, but they are not syntenic, and homologs of the genes are not found outside of this genus. The BaGTA genes are widely conserved and usually syntenic within the genus *Bartonella*, with some BaGTA genes occasionally found outside the genus. Both of these GTA systems appear to be of relatively recent origin (Fig. 7). Conservation is much deeper for RcGTA. Complete sets of RcGTA gene homologs are well conserved across the order Rhodobacterales, and occasionally found in other alpha-proteobacterial orders. Additionally, partial sets of the genes are detected in the genomes of many other

Fig. 6 Gene organization in typical DNA phage and GTA gene clusters. (A) Prophage genome integrated in bacterial chromosome. (B) GTA genes in bacterial chromosome. alpha-proteobacteria, including members of the deep-branching order Rickettsiales. This suggests that the origin of RcGTA goes back to the origins of the class alpha-proteobacteria (at least 700 million years).

Although genuine gene transfer by BaGTA has been demonstrated for only one species, *B. henselae*, production of particles with the same properties in terms of DNA content (i.e., 14-kb random fragments) has been observed for additional *Bartonella* spp. The ability of these particles to perform gene transfer warrants further study to determine the level of conservation of GTA functionality within this group, which would provide further support for the idea that GTAs are maintained by cellular organisms due to their provision of benefit(s). For RcGTA, representatives of multiple genera have been documented to make similar particles, and some of these have been shown to mediate gene transfer. Therefore, production of functional GTA particles has been maintained by these organisms over long evolutionary time-frames.

Evolutionary Function(s) of GTAs

For GTAs, it has been assumed that the benefits of transferring random chromosomal genes overwhelms the costs of GTA production. However, this may not be consistent with the current understanding of how evolutionary forces act on gene transfer processes (Fig. 8). The perils of this notion are well illustrated by the mutually contradictory explanations given for regulation of RcGTA and BaGTA production. For RcGTA, production only when the culture growth stalls is said to help stressed cells acquire new genes, but BaGTA production by log-phase cells is said to help fit cells share their genes.

Fig. 8 Schematic representation of evolutionary forces acting on GTA genes and GTA⁺ cells and populations. Upward-pointing arrows, forces causing an increase; downward-pointing arrows, forces causing a decrease; orange arrows, forces acting on individual GTA⁺ cells; purple arrows, forces acting on GTA⁺ populations.

The only known consequences of GTA production are lysis of the producer cell and transfer of fragments of its DNA to recipient cells. Because GTA production is lethal there is no direct benefit to the producing cell. Although regulation of GTA expression is thought to limit this lysis to a very small fraction of the population, it nevertheless represents a significant evolutionary cost of GTA production that must be opposed by evolutionary benefits if the GTA genes are to be maintained. Indirect evidence that such benefits must exist comes from analysis of mutation distributions in both BaGTA and RcGTA genes, which shows strong evidence of purifying selection; that is, natural selection is removing the non-synonymous mutations, which change amino acid sequences and are likely to interfere with the genes' functions. The maintenance of functional GTA systems across long evolutionary time-scales provides additional evidence that these systems must provide benefits of some sort.

The simplest explanation for persistence of GTA systems would be that they are "selfish" entities that exist only to spread the GTA genes to other cells. However, the lack of GTA-specific DNA replication and packaging, and the inability for GTAs to package all of their encoding genes, make this very unlikely. It remains possible that the GTA genes may contribute some other benefit to the producing organism that is not related to GTA production and gene transfer, but such benefits have not been identified.

GTAs as Part of the Virosphere

It is now recognized that viruses are the most abundant biological entities on the planet. In the oceans, for example, viruses typically outnumber cellular organisms by at least tenfold. This realization came from direct counting of virus particles through techniques such as fluorescence microscopy using DNA-binding stains that allow virions to be detected. However, these techniques have limitations and only particles with enough DNA content can be visualized and counted and these techniques would be unlikely to enumerate GTAs due to their packaging of smaller fragments of DNA. Now that we know that multiple organisms make GTAs, it seems likely that some fraction of the "viruses" in nature are in fact GTAs. This might be especially true for some portions of the oceans because of the high level of GTA gene conservation in members of the order Rhodobacterales, which are abundant in the ocean and with multiple representatives demonstrated to produce functional GTAs.

An observation frequently made during viral metagenomic studies is that a proportion of the genes contained within the viruses is always of bacterial origin. There are several possible, non-mutually exclusive, explanations for this. These include contamination of the viral DNA preparation by cellular DNA, the presence of transducing phages in the viral population, the presence of DNA-containing extracellular vesicles in the purified viruses, and the presence of GTAs in the viruses.

Future Outlook

For even the most well-studied GTAs there are many aspects of their biology that remain to be deciphered. For example, although some details are known about regulation of GTA production for some organisms, these are far from complete. Identifying any potential driving force(s) behind GTA evolution and maintenance is an important area for future work to help address the question of possible benefits to producing organisms. Identification of new GTAs in additional organisms will also be important.

Defining Statement

Guidelines and regulations for research with genetically modified organisms (GMOs) have become standardized globally in principle but not yet in practice. Current regulated products from over 40 years of research are greater than 100 microbially derived products used in a variety of medical, industrial, and food applications. Only 12 microorganisms, of which nine are living and three are heat-killed, have been introduced into the environment.

Introduction

Oversight of GMOs continues to differ. Containment of microorganisms is dependent upon the location of the research with the organism, whether inside (contained) or outside (so-called field research), the type of organism (e.g., plant, animal, microorganism) or use (e.g., medical, agricultural, environmental), and the country in which one works. The oversight mechanism for contained research is principally through guidelines developed by scientists and endorsed by the private and public sectors. Outside research is currently overseen by a number of federal agencies. In some countries, such as the United States, there can be overlapping jurisdictions, differing interpretations of legal statutes, and different requirements or standards for compliance by scientists who do research with GMOs in the outside environment. Scientific issues deal with differences in perspective on the risks of introduction of GMOs into the environment, the types of data required before the introduction to conclude that the experiment is of low risk, and the types of monitoring and mitigation practices, if necessary. Nonscientific issues are also considered and include those dealing with legal and social concerns. These differences in interpretation along with considerations of efficacy and commercialization have resulted in few introductions into the environment of microorganisms. The potential is enormous, but progress is impeded by rules and regulations.

[☆]*Change History:* November 2018. S.Tolin and A.Vidaver have updated abbreviations, glossary and introduced small edits in the text of the article and also added further reading and relevant websites. Comments from C. Wozniak of EPA were incorporated.

This article is an update of S.A. Tolin, A.K. Vidaver, Genetically Modified Organisms: Guidelines and Regulations for Research, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 565–577.

Concern Over GMOs

The new biology, dating to the 1970s and usually said to begin with the discovery of recombinant DNA (r-DNA) techniques, enabled scientists to perform modifications of organisms with great precision and to combine DNA of organisms that cannot, in evolutionary time, exchange DNA; yet these recombinants are derived from the DNA of naturally occurring organisms. The scientific community debated hypothetical scenarios about the safety of genetically engineered organisms, and the public questioned the potential adverse effects of organisms with the new combinations of genetic information on humans and the environment. It was argued that such organisms have not been subjected to evolutionary pressures, including survival, dissemination, and selection, and may pose unpredictable risks to humans or the environment. However, it was recognized that genetic modifications can arise by classical or molecular methods, ranging from selection of desirable combinations by farmers or bakers since antiquity to nucleotide insertion or deletion by molecular biologists or more recently by *de novo* synthesis of self-replicating agents from known viral sequences. Beneficial, neutral, and deleterious changes can occur, and will, whether or not microorganisms are manipulated.

Research with GMOs also generated concern that the new organisms may be unpredictable not only in survival and dissemination but also in the possibility that the gene for the modified trait may transfer to nontarget organisms where it might have a different fate and impact. However, gene transfer occurs whether or not humans intervene, and is quite common in certain bacteria harboring promiscuous plasmids. Such gene transfers are thought to have minimal consequences unless selection is imposed. Increasing evidence supports the conclusion that microorganisms, particularly bacteria, usually maintain their fundamental characteristics and their essential identities, and moderate the amount of change that can be absorbed by known and unknown mechanisms. Principles for assessing risk of GMOs, as developed in scientific and public forums that led to guidelines and regulations, include the premise that if one begins with an organism that normally exchanges genetic information with another organism, exchange by r-DNA techniques should pose no risks that do not occur naturally. A second principle is that if insertion of DNA into a benign or beneficial organism imparts a neutral or beneficial trait, the probability of harm from transfer of genetic information is minimal.

History of US Guidelines and Regulations Applicable to GMOs

Response to Concerns that Enabled Research

The concern over the potential risks of GMOs led to a call for the initiation of various mechanisms for the oversight of research conducted throughout the world. Although new laws were proposed at the time, the oversight was first in the form of guidelines, a set of principles and practices for scientists to follow, and physical facilities to minimize escape of organisms. Regulation by laws applicable to certain genetic modification processes or organisms used for certain purposes is explained later. The legal profession claims that this is the first case in which hypothetical or speculative risks have become the basis for regulation.

Codified guidelines date back to the 1970s, when the concerns described above were raised. The decision was made by the US government to give the lead to the National Institutes of Health (NIH) of the Department of Health and Human Services. After several meetings including the Asilomar Conference in 1975, NIH developed guidelines to assure minimization of risk through containment of research involving r-DNA molecules, and to allow research to proceed. The first guidelines were published in 1976, and established a public meeting body of peers and nonscientists. This group was assembled as the NIH Recombinant DNA Advisory Committee (RAC) by the Office of Recombinant DNA Activities (ORDA), and was given the task of reviewing all r-DNA experiments within the United States and to revise the guidelines as needed to incorporate their recommendations. The RAC has met periodically for over 40 years, and has revised, updated, and republished the guidelines numerous times, most recently in April 2016. With this revision, the scope of the guidelines was broadened to include research on synthetic nucleic acid molecules. All previous versions of the Guidelines since 1995, and minutes of RAC meetings, are publically available from the NIH website (<https://osp.od.nih.gov/biotechnology/nih-guidelines/>). The name of the office within NIH that is responsible for the RAC and the guidelines is now the Office of Biosafety and Recombinant DNA Policy in the Division of Biosafety, Biosecurity, and Emerging Biotechnology.

The RAC was to assess the risk of each proposed experiment and recommend containment conditions under which it thought the risk would be minimal for laboratory workers and the environment. Each time the RAC made a recommendation on an organism and containment level, the decision was added to the guidelines after it had been acted on by the director of NIH. The resulting guidelines spelled out the recommended facilities and procedures for safety to individuals and to the environment. They included such specifics as the type of pipetting procedures one should use, what clothing to wear, and proper sterilization, air filtration, and decontamination and mitigation procedures.

Within a short time, most of the microorganisms and experiments had been assigned a containment level, and the responsibility for overseeing such experiments was decentralized and delegated to local institutional biosafety committees (IBCs) and to other institutions in other countries.

Many experiments to modify common laboratory strains of bacteria and yeast were judged to pose no risk and were exempted from the guidelines or any containment requirements. Research with other microorganisms, including viruses, required containment no greater than one would use for research with the microorganisms that did not involve genetic modification experiments. These assignments were generally consistent with the classification of human-associated microbes into risk groups by biomedical authorities, such as the Centers for Disease Control (CDC) in the United States. Other countries soon followed suit, many adopting the US guidelines.

Approval Mechanisms for Previously Prohibited Experiments

The initial guidelines prohibited culture of GMOs in volumes of greater than 10 L, the rationale being that accidental spillage of smaller volumes was of lower risk. This restriction was challenged by the pharmaceutical manufacturer, Eli Lilly, whose scientists had discovered a method for producing human insulin in the common bacterium *Escherichia coli*. The argument made was that large-scale fermentation was used safely, without organisms escaping into the environment, for a number of human pharmaceutical products. The RAC recommended lifting this prohibition and added an appendix that provided guidance to large-scale fermentation activities.

The initial guidelines also prohibited deliberate release of r-DNA-modified organisms into the environment, whether for research purposes or other activities. Scientists conducting research with plants and with microorganisms associated with plants argued that field experiments were often conducted and were the equivalent of clinical trials with humans and animals to select for and demonstrate efficacy and responses to different environmental conditions. A working group of the RAC recommended elimination of the prohibition, and changed the activity to “planned introduction into the environment” that required RAC review and NIH approval. Requests for conducting research with plants and plant-associated bacteria were considered by the RAC and approved, but never conducted. After legal review, it was deemed that NIH could not approve such experiments as there was no program within the agency encompassing such research. The US Department of Agriculture (USDA) research agencies established a biotechnology research advisory committee whose members had greater expertise to review agricultural and environmental experiments, but authority was never given to this committee or to the USDA to issue approvals.

Only experiments with human gene therapy and the occasional new organism or special request for change in the recommended containment level now require review by the RAC and approval of the NIH. Most recently, the NIH will no longer accept new human gene transfer protocols for the protocol registration process under the *NIH Guidelines*, or convene the RAC to review individual human gene transfer protocols (<<https://osp.od.nih.gov/biotechnology/nih-guidelines/>>—August 2018).

Guidelines to Regulations

Federal government activities, spurred by the perceived benefits of GMOs in agricultural and environmental applications, reviewed all applicable laws and regulations governing potential products of biotechnology. A document was issued in the mid-1980s on the regulation of products, and thus the research leading to their development, to the agencies that regulated similar products that were not genetically modified by rDNA techniques. Thus approval for GMOs for introduction into the environment in the United States was transferred to regulatory agencies. The regulatory arm of the USDA used current laws governing veterinary medicine products and plants within the Animal and Plant Health Inspection Service (APHIS). The US Environmental Protection Agency (EPA) used the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) to regulate pesticides and the Toxic Substances Control Act (TSCA) to regulate toxic substances, including so-called ‘new’ organisms derived through transfer of intergeneric or synthetic DNA. GMOs considered as food or food-associated products became subject to the Federal Food, Drug, and Cosmetic Act (FFDCA) of the Food and Drug Administration (FDA). These changes to regulation were encouraged by industries as they provided a route by which products could be approved for commercialization. However, obtaining experimental use permits for field trials became an onerous activity for both academic and private researchers. The impact of regulations on GMO applications has been extensively debated in the last 40 or more years.

Thus the evolution of guidelines and regulations applicable to GMOs has led to a matrix of responsibilities for oversight depending on the stage of development, the intended application, and the location of the research as summarized in Table 1.

Compliance and Approvals for Contained Research Under the NIH Guidelines

Classification of Experiments

Since 1978, compliance with NIH guidelines has been mandatory for all research utilizing rDNA techniques at an institution receiving federal research funding. The guidelines are promulgated only for NIH-funded research, but all other federal agencies funding research also require compliance with these guidelines. Although not required, privately funded and industrial laboratories

Table 1 Types of oversight of genetically modified organisms^a

<i>Location and stage of development</i>	<i>Oversight</i>
Laboratory, greenhouse, animal pen ^b	Decentralized oversight from federal agencies in the form of guidelines
Large scale fermentation	Guidelines from federal agency for oversight
Small-scale field research ^c	Guidelines and regulations: Combination of decentralized and federal oversight
Scale-up or large-scale testing	Federal and state regulations
Commercial products	Federal, state, international regulations

^aReflects current practices: The degree of oversight differs in each country, and among different funding and regulatory agencies.

^bFor unmodified organisms (naturally occurring, chemically altered, spontaneous or selected mutants), standards of practice apply in research, whether conducted by the public or private sector.

^cIncludes tests on land and in enclosed waters.

adhere to the guidelines, because some agencies approving commercial products of biotechnology research began to require compliance with the guidelines for product approval.

An investigator working with or constructing a GMO must first determine whether or not the research is exempt from or subject to the guidelines. If the research is exempt, no further action is needed but it is recommended that the containment conditions in biosafety level 1 (see below) be followed during the course of the research. If the particular research is not exempt from the guidelines, the biosafety level recommended for the research is specified in Section III of the guidelines, and certification of compliance is the responsibility of the local IBC before or at the time the research is begun (notification).

Classification of Organisms Based on Risk

Appendix A of the guidelines lists organisms exempt from oversight because they naturally exchange genetic information with each other. Only bacteria are currently listed. Sublist A is the largest and includes all species in the genera *Escherichia*, *Shigella*, *Salmonella*, *Enterobacter*, *Citrobacter*, *Erwinia*, and certain species in the genera *Pseudomonas*, *Serratia*, and *Yersinia*. Sublist B includes eight species of *Bacillus*. Sublists C and D each list three species of *Streptomyces*. Sublists E and F include certain species of *Streptococcus*. If the research is not exempt, the investigator determines the recommended containment depending on the type of experimentation and the risk level of the organism and vector system being used. The IBC certifies compliance for this level, in accordance with Section III of the guidelines.

Risk levels for many microorganisms can be found in Appendix B, *Classification of Human Etiologic Agents on the Basis of Hazard*, and are summarized in Table 2. Included are those biological agents known to infect humans as well as selected animal agents that may pose theoretical risks if inoculated into humans. The listing in Appendix B reflects the current state of knowledge and serves as a resource document for commonly encountered agents, but is not intended to be all inclusive. The classification is based on agent risk assessment information compiled by the CDC; further guidance on agents not listed in Appendix B may be obtained from CDC and the Belgian Biosafety Server websites. The US list is reviewed periodically by a special committee of the American Society for Microbiology, and its recommendations for changes are presented to the RAC for consideration as amendments to the NIH guidelines. Organisms that are not agents of human disease are not included in the listings in the guidelines. Those microbial agents associated with plant and animal diseases are subject to the regulations of the Plant Protection Act, the Animal Health Protection Act, and the Virus-Serum-Toxin Act, under the authorities of the USDA APHIS. Permits from the USDA APHIS are required for transporting interstate any plant pathogenic agent between laboratories, and specific containment conditions are specified on a case-by-case basis, often with on-site inspection by USDA personnel. Receipt of a regulated article (i.e., a microbial culture) by a laboratory is accompanied by terms of final disposal and use. Transfer to another laboratory will require amendment of the permit conditions.

In Appendix C, exemptions are explained and listed. Exempt research includes using, as host organisms for cloning DNA, *E. coli* K-12, *Saccharomyces cerevisiae* and *Saccharomyces uvarum*, asporogenic *Bacillus subtilis* and *Bacillus licheniformis*, and also certain extrachromosomal elements of Gram-positive organisms propagated and maintained in them. Using DNA from organisms that are risk group 3, risk group 4, or otherwise restricted is not exempt. Cloning potent vertebrate toxin genes is also not exempt, except under conditions explained in Appendix F. Appendix E lists certified cloning vectors, including plasmid, bacteriophage, and others, for each of the above host systems and for *Neurospora crassa*, *Streptomyces*, and *Pseudomonas putida*. The rationale for the safety of these host-vector systems, and the process for certification of new systems for a particular degree of biological containment based on the survival of the host and the potential for transfer of the vector to another organism, is explained in Appendix I—Biological Containment. Appendices P and Q also address biological containment for plants and animals and associated microorganisms.

Table 2 Classification of human etiologic agents by risk group^a

Risk Group	Definition	Examples
Risk Group 1 (RG1)	Agents that are not associated with disease in healthy adult humans	<i>Bacillus subtilis</i> , <i>E. coli</i> K-12, Adeno Associated Virus-types 1–4
Risk Group 2 (RG2)	Agents that are associated with human disease which is rarely serious and for which preventive or therapeutic interventions are often available	Forty bacterial genera, including <i>E. coli</i> O157:H7; 12 fungal genera; 31 parasites; common viruses in 18 families
Risk Group 3 (RG3)	Agents that are associated with serious or lethal human disease for which preventive or therapeutic interventions may be available (high individual risk but low community risk)	Nine types of bacterial agents, including <i>Rickettsia</i> ; 2 fungi; severe viruses in 8 families including Hanta, HIV; CJD and other prions
Risk Group 4 (RG4)	Agents that are likely to cause serious or lethal human disease for which preventive or therapeutic interventions are not usually available (high individual risk and high community risk)	Extremely severe and emerging viruses in six families, including Lassa, Ebola, undefined hemorrhagic fever agents

^aFrom NIH Guidelines and CDC Classification of Etiologic Agents. See Table 3 for URLs.

New regulations after 11 September 2001 require biosecurity oversight for certain high-risk agents identified as potential agents that can be used in bioterrorist events. These regulations supersede the above, and apply to human, animal, and plant microbial agents designated select agents by CDC and USDA. The website should be consulted to access current information, as the list changes periodically (<https://www.selectagents.gov/>).

Physical Containment and Practices

Detailed descriptions of physical facilities and practices to be followed by researchers to ensure containment of organisms and safety to workers and the environment in standard laboratory research are given in Appendix G of the US, NIH Guidelines. Four biosafety levels, BL-1 through BL-4, represent increasing stringency and control of the environment. Their use generally corresponds to research with organisms in the risk group 1–4 classification of etiologic agents (Table 2), irrespective of rDNA technology being used.

Appendix K specifies physical containment facilities and practices for large-scale uses of rDNA molecules, and Appendices P and Q specify physical and biological containment facilities and practices for experiments involving plants in greenhouses and animals in animal pens, respectively. In practice, APHIS may assist the investigators and the IBCs in certifying containment for these facilities. Other appendices deal with shipment (H) and human gene therapy (M).

Compliance and Approvals for Research With Planned Introduction Into the Environment

Any research with GMOs that is to be conducted in facilities that are not specified in the NIH guidelines is considered a planned introduction into the environment. Experiments involving introduction of GMOs into the environment were first reviewed and approved by the RAC in the early 1980s. However, they were not conducted until 1986 after investigators received approval for their research from regulatory agencies. This action signaled the beginning of oversight for such experiments by centralized regulatory authorities rather than through guidelines that describe principles and practices for confinement of the GMO to minimize risk.

In the United States, regulatory authority over research involving genetically engineered microorganisms introduced into the environment falls primarily with the USDA-APHIS and/or the EPA. A GMO intended for field evaluation is regulated by both USDA-APHIS and EPA, under the Plant Protection Act and FIFRA, respectively, when it contains DNA sequences from a plant pest and the intent is to use the microorganism as a biopesticide.

If the purpose of the GMO is for bioremediation of waste or contaminated soil, production of biofuels, biosensors or manufacture of chemicals, EPA's Office of Pollution, Prevention and Toxics (OPPT) regulates the GMO under TSCA. Microbes arising from transfer of DNA derived from a species in a genus other than the genus of the recipient organism may be subject to TSCA oversight as "new chemicals." One critical aspect of oversight under TSCA is the commercial intent of the producer. Research performed for investigational purposes or proof of concept would not likely fall under this Section 5 TSCA authority. However, pesticidal intermediates (e.g., bacteria carrying marker transgenes with ultimate intent of developing a pesticide) may require a TERA (TSCA Experimental Release Application).

The FDA has oversight for GMO microorganisms which are intended for use in production of food and feed products, including enzymes, nutraceuticals and microbes used in fermentation (e.g., *Saccharomyces cerevisiae*). Laboratory research for these purposes is not directly regulated by FDA, but compliance with NIH Guidelines is required by FDA. However, if the microbially produced entity is going to enter into commerce (i.e., the food and feed supply), conditions used in the manufacturing process will be scrutinized as part of the review process under FFDCA. With the advent of genetic engineering of animals for food or pharmaceutical production, FDA has applied their new animal drug application and investigative new animal drug (INAD) authorities under FFDCA to GMO salmon for food and more recently to sterile mosquitoes developed for the intent of decreasing populations of disease incidence or virus titer from vectors such as *Aedes aegypti*, the vector of dengue fever. GE mosquitoes intended for population reduction are now the purview of EPA as pesticides. INAD status may be needed to transport a GMO across state lines if it qualifies as a "drug" under FFDCA. Details are given in an Animal and Veterinary section of the FDA website.

None of these agencies has a codification similar to that of NIH for contained research. Instead, each introduction is treated as a distinct case and an application must be submitted by the investigator to the appropriate federal agency for permission to conduct the research. Each of the agencies has published policy statements or has issued proposed or final rules describing how regulations they enforce are applicable to research with GMOs. More detailed descriptions of legal and jurisdictional issues can be found in the "Further reading" section. The current status of each agency and of approval processes can be obtained most readily by viewing materials online.

For example, the EPA Final Rule under the TSCA, published in the 11 April 1997 Federal Register (62 FR 17910–17,958), is accessible at the Office of Pollution Prevention and Toxics site. An 80-page document entitled "Points to Consider in the Preparation of TSCA Biotechnology Submissions for Microorganisms" is available from the EPA. In this regulation, research and development activities are subject to TSCA if funded, in whole or in part, by a commercial entity, or if the researcher intends to obtain an immediate or eventual commercial advantage from the research. Microorganisms that are covered are those new microorganisms that are intergeneric and have been formed by the deliberate combination of genetic material originally isolated from organisms of different taxonomic genera. Intergeneric microorganisms also include those containing a mobile genetic element

(including plasmids, transposons, viruses) first identified in a microorganism in a genus different from the recipient microorganism. Reporting to or obtaining approval from the EPA is required before manufacturing such organisms in containment or releasing them experimentally. However, an exemption is provided for researchers conducting small-scale field tests with the nitrogen-fixing bacteria *Bradyrhizobium japonicum* and *Rhizobium (Sinorhizobium) meliloti*, provided certain conditions are met. The field test must be less than 10 acres in size and containment measures must be employed to limit dissemination of the organism. Researchers complying with the NIH guidelines may also be granted an exemption from the EPA for contained research in closed systems for the following organisms: *Acetobacter aceti*, *Aspergillus niger*, *Aspergillus oryzae*, *Bacillus licheniformis*, *Bacillus subtilis*, *Clostridium acetobutylicum*, *Escherichia coli* K-12, *Penicillium roqueforti*, *Saccharomyces cerevisiae* and *Saccharomyces uvarum*. This is based upon a history of safe use of the organism, safety of the DNA introduced, and documented conditions for containment and inactivation of the microbe to keep any releases from the production facility to a minimum. It should be noted that EPA is proposing to add two microorganisms (specific strains of the fungus *Trichoderma reesei* and specific subspecies of the bacterium *Bacillus amyloliquefaciens*) to the list of 10 recipient microorganisms (40 CFR 725.420) that are eligible for exemptions from full chemical notification requirements under the Toxic Substances Control Act.

Oversight Mechanisms

Standards of Practice

All trained professionals learn and adhere to certain accepted procedures and practices with respect to safety and to the appropriate scientific methods for the profession. Most persons trained in microbiology and related disciplines using microorganisms are exposed to the same standards of practice that are used in training medically oriented professionals. These include safe preparation, use, and disposal of inocula and inoculated organisms, including inoculated plants or animals, and appropriate decontamination and mitigation procedures such as sterilization in contained facilities or incineration of animals or burial of plant material.

Standards of practice for all scientists include procedures appropriate for conduct of experiments; the use of data, including statistical analysis techniques; publication ethics and standards; and sharing of biological materials after publication of results. Standards of practice in the open environment are particularly evident in agricultural and forestry research; the sites are evaluated, plots are designed to enable statistical analysis of results, criteria for evaluation of results are widely distributed and agreed upon through peer review, and results are disseminated through various publications. Practices to preclude significant risk to the environment and to mitigate possible untoward effects are routinely considered and used by researchers.

Guidelines and Directives

Guidelines may be considered a statement of policy by a group having authority over that policy. Sometimes such guidelines are also published as “points to consider.” These guidelines offer assistance to investigators, and do not have legal authority, except if required by a funding or regulatory agency. Guidelines are generally considered far more flexible than are directives or regulations. Guidelines that have been adopted worldwide for contained research with GMOs are those originating from the US. The NIH guidelines have been considered de facto regulations, as commercial entities have also adopted them as standards of good manufacturing practice. Since NIH is not a regulatory agency it can require compliance only for its grantees. By policy, applicable research sponsored by other Federal agencies is to be conducted, de facto, in compliance.

European and international guidelines contain some questionable analyses. The International Codex Alimentarius Commission oversees food production. A key safety goal, number 60 (2003), is to determine “whether the food produced using a recombinant DNA microorganism is as safe as the conventional counterpart.” It omits a major consideration dealing with safety of microorganisms, namely the assessment of potential benefits of rDNA. Thus, the possibility that food could be even safer, for example, lower or no allergens in peanuts, is not addressed.

Directives, particularly those issued by governments, are orders or instructions. Directives are currently an overarching method of oversight implemented by multinational groups such as the European Union (EU). Countries are being urged to implement the directives within the next few years that would ideally harmonize oversight within the EU. However, individual countries would still have the prerogative of overseeing the details of such directives or even making them more stringent. Groups such as the United Nations, the World Health Organization (WHO), the Organization for Economic Cooperation and Development (OECD), and others also make informed statements for governments to consider as they develop their own oversight policies and mechanisms.

Regulations

Regulations are laws or rules to control or govern procedures or acts. In the case of GMOs, some countries have implemented new laws for oversight of certain microorganisms and field tests, especially in Europe. In other countries, no laws are currently applicable. In the United States, legal interpretations of current statutes have resulted in extensive oversight of research involving field trials and even commodity imports. Details can be obtained from websites of agencies and other sources listed in Table 3. The laws have legal penalties for noncompliance, whether in the public or private sectors. This type of oversight in the United States has resulted in an elaborate permitting, evaluating, interagency coordination, and reporting system that may be viewed as time-consuming, cumbersome, and costly to some, and inadequate to others. In addition to federal and national laws, other governmental entities such as

states or cities have enacted their own regulations, compounding the difficulty of conducting field research. Confidential business information is protected in all cases, including oversight by guidelines or by competent authorities, unless such information relates to safety issues. There are also multilateral treaties such as the Cartagena Protocol on Biosafety that are legally binding for transboundary transfer of certain classes of Living Modified Organisms that may pose a threat to biodiversity. However, a review by Kinderlerer (2008) concluded that few countries have laws in place to deal with GMOs under the biosafety protocol, and view the risk as palpable.

Appropriateness of Guidelines and Regulations

Contained Research

The conditions described in the NIH guidelines have served as a codification of practices for conducting research with both unmodified and modified organisms within a traditional laboratory setting and for large-scale fermentations with many microorganisms to produce many products of biotechnology. There is no indication that exempting certain organisms from containment requirements, or conducting most other experiments at the lowest containment conditions, has caused any problem to individual workers or the environment. The guidelines have served both national and world interests well for nearly 45 years. Although mandatory only for federally funded research, private companies have embraced them and established their own IBCs.

Conditions for conducting research with other organisms that require other conditions for optimum growth, such as plants, animals, and microorganisms associated with them, have also been described in the guidelines. The practices are based on those

developed as standards of practice in research, and there is no evidence of adverse effects upon the environment when these practices have been followed.

Rapid advances in plant and animal biotechnology, however, have practically made the guidelines for contained research with certain genetically modified plants and animals obsolete. For example, engineered soybean and corn grow extensively in farmers' fields, yet when grown in a greenhouse for research purposes, such plants are not exempt from the NIH guidelines and may be treated by IBCs as requiring containment for research. The guidelines should be modified to give clear exemptions of those plants, as well as microorganisms and animals that have been approved by regulatory agencies for commercial use in the environment.

Rationale for Concerns

The concern over GMOs resides partly on a perceived increase in the ability of the organism to survive or persist. Thus, some scientists and consumers argue that oversight of GMOs should be as stringent as for toxic chemicals, physical disruptions such as water control projects, or exotic organism introductions. The strongest argument for these concerns is voiced by persons who compare the risks of GMOs with those of introducing exotic organisms. The appropriateness of this analogy can be questioned because there is generally a great familiarity with the organism being modified and the trait being introduced, and the fraction of the new genetic information is very small. Engineered organisms to date contain less than 10 introduced genes, versus many in standard and exotic hybridization classes, as well as 4000–20,000 for an exotic species, which can be familiar or unfamiliar, with entire genomes.

There is also a perception by some that, should there be a problem with survival or dissemination of a microorganism, nothing can be done. Essentially, the assumption is that once the gene is out, it cannot be recalled. However, both orderly and inadvertent movement and dissemination of microorganisms occur repeatedly because of their presence in humans, plants, animals, and inanimate objects that are moving throughout the world at increasing rates. There are also long-standing environmental practices that are in use to decontaminate or mitigate unwanted effects of microorganisms. Such practices are known for microorganisms associated with food production, plants, and animals as well as for free-living microorganisms. Immediate decontamination methods include, among others, burning, chemical control, and sanitation by various means. Short- and long-term methods are abundant for plant-, animal-, and human-associated microorganisms, since a great deal of research on developing mitigation methods is conducted by scientists in the disciplines of plant pathology, veterinary medicine, and human medicine. Many of these deal with management practices and the use of genetic resistance and application of biological control organisms. Immunization of humans and animals, including the use of genetically modified microorganisms for vaccines, is another type of long-term management practice to mitigate the effects of microorganisms.

Differences in microorganisms and their effects have long been recognized by consideration of risk and resulting designations into risk groups. In addition to previous risk groups applicable to humans, animals, and plants (see "Belgian classification for micro-organisms based on their biological risks—Definitions" in the website) the United States has classified microbes of public health and national security concern into select agent categories based on ease of transmission, severity of morbidity and mortality, and likelihood of use in bioterrorism. These were classed as select agents and toxins, which legally restricts the possession, use, and transfer of these agents. However, in 2007, the US CDC issued some exclusions depending on the genetic modification. Many parts of the world seem to be operating on the principle of paralysis by analysis with respect to commercial use of genetically modified microorganisms. Recent work on nitrogen fixing microbes may help to change this attitude as nitrogen is key to agriculture and the potential benefits of these novel microbes are immense.

Research Involving Planned Introduction Into the Environment

Scientists had many concerns about the safety of planned introductions and examined such introductions in multiple ways. In 1987, the US National Academy of Sciences made major conclusions regarding risk, one of which stated that there is no evidence that unique hazards exist, either from the use of rDNA techniques or from the movement of genes between unrelated organisms. Further, the risks of the introduction of GMOs carrying rDNA are similar to those associated with the introduction of unmodified organisms and organisms modified by other methods. The final conclusion was that assessment of risks of introducing GMOs carrying rDNA into the environment should be based on the phenotype of the organism and the environment into which it is introduced, not on the method by which it was produced—the product, not the process.

In going further with the assessment of risk, another study by the National Academy of Sciences in 1989 posed three fundamental questions to assess risk: (1) Are we familiar with the properties of the organism and the environment into which it may be introduced? (2) Can we confine or control the organism effectively? (3) What are the probable effects on the environment should the introduced organisms or genetic traits persist longer than intended or spread to nontarget environments? Similar questions for focusing on risk were elaborated by the Ecological Society of America in greater detail. Questions still remain on how to scale regulatory oversight on the basis of risk.

The principles espoused in the preceding types of publications have played a major role in the risk assessment policies developed by international bodies such as the EU, the OECD, and others. Various entities have provided for the responsible oversight of rDNA research and field trials in countries in which formal oversight mechanisms are lacking.

Concerns Over Genetically Modified Domesticated Organisms in Agriculture and the Environment

Virtually all domesticated organisms used in the production of food, feed, and fiber have been genetically modified over long periods, including certain live domesticated microorganisms used in making bread, beer, wine, various types of cheese, yoghurt, and other fermented foods. Selected microorganisms that have been shown to be beneficial are also widely used in the environment. These uses include, among others, microorganisms that fix nitrogen and provide nutrients for trees and other plants (mycorrhizae) as well as those used in sewage treatment plants and oil drilling. Also, naturally occurring pathogenic microorganisms are used in the testing of domesticated plants to ascertain their disease resistance. In such critical tests with known pathogenic organisms, there has been no documented case of untoward effects, such as a plant disease epidemic, arising from such standard field trials.

It is widely accepted that the first step in risk assessment, whether in containment or in confined field trials, is identifying the risk by determining how much is known about the parental organism. It is also recognized that the risk can be minimized by the preferential selection of parental organisms that are generally recognized as safe because of their long history of use. In the oversight of food, such foods are categorized as GRAS or generally recognized as safe (US FDA). A similar category might be considered for microorganisms that would be introduced into the environment: GRACE, or those microorganisms that are generally recognized as compatible with the environment (our proposal).

Examination of the food safety issues associated with genetic modifications has led to the conclusion that potential health risks are not expected to be any different in kind than those associated with traditional genetic modifications. All such evaluations rest on knowledge of the food, the genetic modification, the composition, and relevant toxicological data. A recent international body concluded that rarely, if ever, would it be necessary to pursue all such evaluations exhaustively. There is reasonable agreement that a threshold should exist for regulation, or even of concern below which further evaluations on a genetically modified food product or its individual components need not be conducted. The International Food Biotechnology Council recommends flexible, voluntary procedures between food producers and processors and a regulatory agency.

Regulation of Field Research

At the present time, there is no decentralized body in any nation for oversight of field research that is comparable to the IBC for contained research. The USDA published (Federal Register, 1 February 1991) a draft of guidelines for conducting research under confinement in the open environment prepared by the Agricultural Biotechnology Research Advisory Committee of scientists (ABRAC). However, these guidelines were never implemented even though they provided generalized principles for assessing and managing the risks of microorganisms, as well as plants and animals that have been genetically modified, particularly by r-DNA. The principles laid out in these guidelines were sufficiently generic that they were to be applicable throughout the world. Later in 1995, this USDA committee developed performance standards specifically for research with genetically modified fish and shellfish, since no statutory authority existed for oversight by a regulatory agency.

In many countries, the oversight of GMOs is essentially the same as for unmodified organisms, except for the contentious issue of planned introduction into the environment. In countries such as the United States and Canada, a sizable bureaucracy has been built up to oversee both research and product development. Even though the risks remain speculative, the fear of litigation and unknown hazards has served to minimize the actual number of introductions, particularly of microorganisms. Of the approximately 12,500 tests of plants, animals, and microorganisms introduced into the environment for research, less than 10% have been microorganisms. Most of these microorganisms were modified to have marker genes that enabled them to be monitored in the environment. The first functional genes added to microorganisms and field-tested in the early 1990s were those encoding an insecticidal toxin from *Bacillus thuringiensis* added both to a pseudomonad and to a coryneform bacterium. In the former case, the modified organism was killed before it was released. In the latter case, in field trials to test for insecticidal activity, plants inoculated with the GMO were successfully protected from the European corn borer. But commercialization of this gene succeeded only when it was introduced into the genomes of corn (maize) and cotton.

Commercialization

Some scientists are more concerned about the widespread adoption of a beneficial organism in commerce, rather than about small-scale field research, because greater exposure is likely to increase the probability of risk.

In over 40 years of research on microbial GMOs, thousands of papers have been published and patents issued. Some products of GMOs are widely known and used, yet most are not recognized, nor can most of them be easily determined. Selected products are described in Table 4 to show that virtually all of them are simply derived from microorganisms. We were able to confirm that only 12 microorganisms were commercialized for use in the environment at the time of this writing; some previous products have not been commercially successful and have been removed from the marketplace. Vaccines, however, have been commercialized either as whole viruses or as derived proteins and killed vaccines.

There are about 60 nonduplicative pharmaceutical products for human health (BIO), about 35 food and industrial applications (Europa Bio; information no longer available without membership charge), and two whole bacteria, one live (*A. radiobacter* K 1026) and one killed before use (*P. fluorescens*, with a gene for *Bacillus thuringiensis* δ endotoxin). Viruses are used as vaccines and as insecticidal biopesticides. Regulations on enzymes are not standardized in Europe and probably elsewhere. Not included: Bacteriophage-resistant mutants, bacteriocin producers, naturally selected mutant bacteria and fungi for bread, milk, cheese, and beer.

Needs, Challenges, and Options

Currently, there is no global database on regulations and oversight for genetically modified microorganisms, nor for commercialized products. While a minority of countries do not differentiate oversight on the basis of process, for example, the United States, the majority still do. Hence, the compilation of information would lend transparency to the public, regulators, and those in the commercial sector. The estimate of greater than 100 products (Table 4) is based on accessing a wide variety of sources; only 12 of these products are released into the environment as whole microbes, and three of them are heat-killed before release. Of the 194 recognized countries at the time of this writing, only about 15 have accessible information on regulations and products. However, the number of new websites and information sources on commercial biotechnology products is increasing, and our search is not exhaustive.

We have been unsuccessful in obtaining information on regulations and products from various segments of governments, industry, academic biotechnology institutes, and the International Union of Microbiological Societies (IUMS). The searchable database of worldwide use of genetically modified plants hosted by the Center for Environmental Risk Assessment (formerly hosted by Agbios) has been decommissioned and is no longer available for search and discovery. An annual summary of engineered crop plants in commercial agriculture assembled by ISAAA is available as well as a searchable database (<http://www.isaaa.org/gmapprovaldatabase/default.asp>). Many of the GM plants contain genes of microbial origin that impart viral, insect, or herbicide resistance traits. There is no database on microbial gene inserts into commercially grown animals.

The objectives of a sound oversight policy are to develop a sensible, scientifically based policy that is consistent with a reasonable and accepted degree of safety (rarely absolute or ensured safety). Regulatory agencies also recognize procedures that do not pose an unreasonable risk to humans or the environment, that is, one cannot be absolutely certain that no deleterious effects can occur. Oversight ideally should balance risks with expected benefits. Many issues that deal with GMOs, particularly introduction into the environment, are subject to change and remain unresolved. These include the following:

1. The scope of oversight: What organisms or parts of organisms (genetic elements and sequences) should be subject to oversight?
2. By whom and at what level (e.g., professional organization, standards of practice, IBCs, local regulatory bodies, federal agencies, or some combination) should oversight be conducted? Should all experiments be examined at a federal or country level or can some be decided upon at a local level? Decentralization of authority to make decisions on field releases has not yet occurred, although APHIS has expedited approvals for many plants.
3. Can consistent definitions be developed? Definitions differ among agencies and countries and can lead to problems in legal interpretations. The meaning of the phrase “release or planned introduction into the environment” and even “pathogen” or “pesticide” are yet to be agreed upon. For example, the EPA uses plant-incorporated protectant as a name for the class of pesticidal substances based on use of microbial components engineered into plants with the intent of making disease- or insect-resistant plants. This also affects whether different considerations apply to plant pathogens that are applied as beneficial biological control agents.
4. To what degree should the manner of open and peer review be part of policy-making? What appeal procedures, if any, should there be for scientists and others disagreeing with the oversight bodies?

5. Decision making: Who should decide whether approval of field-testing is needed? Is it the public, the scientists, or the courts? What role is there for common sense? Should the decision be based on risk alone, or include other factors such as socioeconomic considerations?
6. Should there be a “sunset” clause on termination of oversight of research with some organisms or certain types of experiments?

There has been general agreement that a centralized database for field trials would be desirable in order to compare information, including negative results that are not always published. The USDA through its Information Systems for Biotechnology program and the OECD through its Biotrack monitoring database have compiled a great deal of this information. As of September 15, 2017, on-line news reports from the ISB website have been archived, however, the data and information on permits and notifications issued by APHIS are exclusively available on USDA-APHIS websites (https://www.aphis.usda.gov/aphis/ourfocus/biotechnology/brs-news-and-information/2017_brs_news/permit_data); (<https://www.aphis.usda.gov/biotechnology/check-status>). Whether or not these activities serve the purpose of the scientific and commercial community and allay the concerns of the public remains to be seen. Thousands of tests worldwide have been conducted up to the present time and no unpredictable effects have been detected. However, it can be argued that such effects may occur in later years, and hence monitoring will be necessary to assess any problems that might arise. Another question that remains unanswered is how long monitoring should occur, compared with wild-type organisms.

Given the different views of different countries and applicable laws, global agreements on oversight likely will not be forthcoming. However, there is reasonable general agreement on standards of practice through the scientific and professional societies of the world for conducting research. There are also areas of reasonable agreement in principle, acknowledging that the process by which a genetic modification is made is not as significant as the effects of that modification, that is, the phenotype. The same degree of oversight is not applied to unmodified organisms and organisms modified by traditional and newer (gene-editing) approaches. Hence the process of modification is still the trigger for oversight. A second area of agreement is that familiarity or knowledge of the organism and its modification are likely to be good predictors of the characteristics of the modified organism. A third is that knowledge of the ability to confine an organism or mitigate its effect, if need be, offers a reasonable indicator of expected risk and of the potential for its management.

Future Benefits and Concerns

Differing perspectives remain on the safety to humans and the environment of GMOs, particularly those that have been modified by rDNA techniques. The concerns are particularly high with respect to the use of microorganisms in the environment. Discussions are likely to continue for several more years. It is too early to predict whether or not such tests will go forward with reasonable ease, given the stringency of the requirements to conduct the tests. The scientific concerns may not warrant the expenditure of time, effort, and money to conduct field research, since risks unique to GMOs have not yet been identified. The same question could be asked about the oversight of contained research.

Several potential oversight mechanisms would be commensurate with risk assessment and risk management, and have been demonstrated as effective for laboratory research. These could include (1) categorical exclusions, (2) only notification requirements, (3) review and approval by a local organization (e.g., IBCs), (4) review and approval by a Federal agency with an advisory group consisting of members familiar with the relevant research area, and (5) review and approval by an international agency, in cooperation with a member country.

A reasonable policy of oversight will encourage research with GMOs, especially those modified by rDNA techniques. There is no perfect oversight mechanism for any human activity, including environmental releases for research, development, or commercial purposes. There is also the recognition that various viewpoints or perspectives cannot always be accommodated or reconciled. Thus, persons of reason and broad vision will be needed to resolve some of the contentious issues dealing with planned introduction of GMOs into the environment.

Fear overrides any benefits that live GMO microbes could provide, despite recognition that GMOs could be potentially less damaging than the continued application of chemicals, and we do not see this changing in the near future, even in contained environments such as fermentation tanks for alcoholic beverages or for bioremediation in select environments. The notion that mutants, natural gene transfer, and DNA shuffling are acceptable to the public and industry but not deliberately constructed GMOs remains a scientific paradox. In view of the billions of microbes transferred daily in global trade, commerce, and travel, such cautions should be reexamined. More derived products are expected in the coming years. An unresolved question is the *de novo* synthesis of new genomes or virus-like replicons and their oversight, whether for beneficial or biodefense purposes. There is also concern about activities or products that increase virulence or pathogenicity of known microorganisms. Most of these products are or would be constructed using rDNA techniques. Whether or not this is the case, the NIH Guidelines added synthetic nucleic acids in 2013.

With respect to accelerated mutagenesis or DNA shuffling (genome editing), at least in plants, only Canada at present has regulations governing their planned introduction into the environment and commercialization. Thus, Canada examines all novel, manipulated plant products, not only those produced by genetic engineering. Genome editing for microbes is still in the research phase and has not yet been used for commercial purposes. Recent technologies for modifying traits by CRISPR/Cas gene editing has increased interest on the oversight and regulation of resulting organisms.

Genetically engineered antimicrobial microbial weapons are being pursued and perhaps other microbial arsenals, but research is not open to public scrutiny. Such agents may be of dual use, that is, for constructive or destructive purposes. Development of recent programs funding research into plant, insect and microbial agents at the Defense Advanced Research Projects Agency for countering accidental or intentional release of disease causing agents does, however, bode well for further field work on a variety of GMO organisms with practical value (<https://www.darpa.mil/program/safe-genes>; <https://www.darpa.mil/program/insect-allies>). EPA has also seen a significant increase in the number of applications for Biotech Notifications the last few years, which are specific for GMO microbes with pesticidal properties, including from academe and small and large companies developing products for disease and pest control.

The benefits of microbial GMOs remain to be more fully explored and managed for multiple purposes. To the extent that oversight occurs, it will continue to play a major role.

Acknowledgment

We are indebted to Dr. Chris Wozniak for current relevant information and advice.

Glossary

Annotation The process of identifying the locations of genes and coding regions in a genome and determining what those genes do.

Database It is a structured collection of records or information.

Genome The complete set of genetic information contained in the DNA of an organism.

In silico Characterization of biological experiments carried out entirely via computer systems.

Metagenome All the genetic material recovered from an environmental sample, comprising genomes of many individual organisms.

Single nucleotide polymorphisms (SNPs) Single-base variations in the genetic material between different individuals of the same species.

Defining Statement

Genome sequence databases are portals to obtain valuable sequence information on microbial sequencing projects. With their rapid expansion and diversification, these resources are becoming virtual environments to explore microbial genomic space at the gene, protein, function, and pathway network level. The applications of these databases range widely from gene discovery to energy alternatives.

[☆]*Change History:* May 2015. Y He updated the statistics numbers of various databases; extended the reference section; removed the original Figure 1 due to its outdated data; updated Table 4; added Table 5 and added introduction to Table 5; and added a new section "Ontology-Based Gene and Omics Data Annotation."

This article is an update of A. Bhattacharyya, Genome Sequence Databases: Annotation, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 174–184.

Introduction

Over the last 20 years, there has been a meteoric rise in the volume of nucleic acid sequences available in the public domain. This trend has been driven to ever-increasing heights over the last decade primarily through improvements in the speed, accuracy, and availability of high-throughput DNA sequencing technologies. Since the sequencing of the first free-living microorganism, the bacterium *Haemophilus influenzae*, the use of high-throughput sequencing and genome assembly has seen the birth of the field of genomics, that is, the study of an organism at the whole-genome level. Moreover, identification of new applications of genome technology, for example, the sequencing of whole environmental microbial populations, referred to as metagenomics, continues to further accelerate the rate of genome sequence information availability. Due to the smaller size of microbial genomes (e.g., bacteria and archaea), a larger proportion of organisms from these domains have been sequenced in their entirety to date compared to eukaryotes. The main focus of this article is to highlight the content and diversity of genome sequence derived databases with particular emphasis on microbial space.

Genome Sequence Repositories

The presence of such large amounts of biological sequence information from genome sequencing projects has led inevitably to the creation of repositories to house these data. In this respect, it is important to discuss historically how such databases came into being. Prior to the recent advent of automated DNA sequencing, scientists had created repositories to accommodate biological sequence information released into the public domain. Thus, in the 1980s, two organizations launched their respective databases. First, the European Molecular Biology Laboratory (EMBL) produced their data library (EMBL-Bank) followed later in the United States by GenBank (Bethesda, the United States) administered by the National Center for Biotechnology Information (NCBI). The largest public repositories of nucleic acid sequences that exist now reside in the three members of the International Nucleotide Sequence Database Collaboration (INSDC; Table 1) that includes GenBank, EMBL-Bank, and the DNA Data Bank of Japan (DDBJ). As a consequence of a data exchange policy implemented by the INSDC member organizations, information is synchronized daily between each data repository, enabling scientists all over the world to have access to and query the latest sequence information.

GenBank and NCBI

Although all sequence repositories synchronize their data every day and thus possess similar content and volume of data, of the three major genome sequence repositories, GenBank receives by far the largest number of sequence depositions, followed by EMBL-Bank and then by DDBJ. Therefore, it is useful to review the types of information focused primarily on microbial organisms, which exists within the public databases maintained by the National Library of Medicine's NCBI. Although the major proportion of resources spent by NCBI remains with the maintenance, curation, and development of GenBank, NCBI provides an electronic web portal to support a variety of other tools and databases for public use. As with any database, information retrieval, that is, the handling of search queries to the database by the end user, is of primary importance. The major search engine for NCBI resources is Entrez. The NCBI Entrez portal provides a query tool to search a variety of other NCBI-related genomic-, proteomic-, and literature-based databases. NCBI Entrez supports text-based Boolean querying of the 42 databases that together contain 990 million records available at NCBI. As of September 2013, the example records include over 101 million DNA and RNA nucleotide sequences, over 94 protein sequences, over 1.1 million taxonomy terms, approximately 11 000 genomes, over 91 million gene expression records, over 1.2 million gene-based sequence clusters in UniGene (nonredundant eukaryotic gene data set), genetic variations in dbSNP (database of Single Nucleotide Polymorphism) (largely eukaryotic), over 95 000 protein structures from the Molecular Modeling Database (MMDB), 168 000 three-dimensional and 12 000 two-dimensional (alignment-based) protein domains, and the biomedical literature via PubMed, PubMed Central (PMC), and Online Mendelian Inheritance in Man (OMIM). A brief overview of some of the more prominent databases within the NCBI suite is given in the succeeding text:

- Trace Archive: The Trace Archive is a database of over 2.1 billion sequencing traces or chromatograms produced from the automated sequencing machines used for genome sequencing projects. The Assembly Archive links the raw DNA sequence information found in the Trace Archive with assembled genome information found in GenBank sequence depositions.

Figure 1 Genome of the industrial butanol-producing bacterium *Clostridium acetobutylicum* ATCC 824D main chromosome present in the Entrez Genome Project database. Courtesy of Integrated Genomics, Chicago, USA.

- **Entrez Genome:** This database contains sequence and map data from the whole genomes of over 1000 species or strains. The genomes represent both completely sequenced genomes and those with sequencing in progress. The database currently contains over 11 000 genomes, including genomes over 2000 eukaryotes, over 33 000 prokaryotes, 4630 viruses, 5700 plasmids, and 6500 eukaryotic organelles (e.g., mitochondria and chloroplasts). Each genome entry in this database is linked to a GenBank sequence file (identified by a unique GenBank accession number) containing the complete or draft DNA sequence information. The GenBank file is a specially formatted file comprising various fields including the organism name, taxonomy, published paper, the entire DNA sequence, all identified open reading frames (ORFs) with positional chromosome coordinates and gene assignments (also referred to as annotations), gene aliases (e.g., *recA* and *mutS*), and various other genome attributes and features. Details of this sort from a complete sequenced genome from this database can be used, with an appropriate tool set, to display a circular map diagram of an organism's genome (Figure 1).
- **Entrez Genome Project:** A supplemental database to Entrez Genome that provides information regarding status of incomplete sequencing projects as well as functional biological attributes of the organism that has or is being sequenced (e.g., taxonomy, why it is being sequenced, motility, and aerobic/anaerobic respiration).
- **Taxonomy:** The NCBI taxonomy houses approximately over 450 000 organisms with one or more nucleotide or protein sequence associated with each organism entry. The taxonomy browser visualizes the position of an organism in the hierarchical NCBI taxonomic ontology tree and is also able to retrieve entries in other NCBI databases (e.g., nucleotide and protein) linked via Entrez.

- **Entrez Gene:** The Entrez Gene database provides a portal to curated sequences and information about genes with links to other NCBI databases and viewers (e.g., Map Viewer, Evidence Viewer (EV), Basic local alignment search tool (BLAST) link (BLINK), Conserved Domain Database (CDD), and other gene-related resources). The information within Entrez Gene is obtained and maintained through international collaborations as well as being subject to curation by NCBI scientists.
- **Entrez Nucleotide:** This is a nucleotide sequence database that comprises GenBank.
- **Entrez Protein:** This is a protein-oriented database assembled from a variety of data sources, including SwissProt, protein information resource (PIR), Protein Research Foundation (PRF), Protein Data Bank (PDB), and translations from annotated coding regions in GenBank and reference sequence (RefSeq) database.
- **RefSeq:** The RefSeq is a rapidly growing information set of over 61 million sequences (e.g., >52 million protein sequences from >51 600 organisms). RefSeq provides curated entries for gene transcripts, proteins, and genomic fragments, plus computationally derived nucleotide and protein sequences.
- **PubMed:** The PubMed database includes over 24 million citations from life science journals dating back to the 1950s. The PubMed citations are linked extensively to other Entrez databases including Nucleotide, Gene, Protein, Structure, and PubChem and provide the connection between sequence records and the primary scientific literature.
- **Influenza genome resources:** The Influenza Genome Project has generated over 12 000 viral sequences housed at NCBI, together with tools for the identification of genetic determinants of viral pathogenicity.

In addition to the databases discussed previously, there are numerous other databases that are part of the NCBI resources. Some of these rapidly growing databases are largely eukaryotic in relevance and content comprising, for example, the following:

- **UniGene database:** UniGene is a nonredundant database containing GenBank sequences and expressed sequence tags (ESTs) clustered into sets of related gene clusters or families. UniGene clusters are linked to the unique gene sequences and associated organism of origin. A set of UniGene clusters are assembly for any organism. In UniGene, human has over 7 million sequences in clusters, including 221 081 mRNAs and millions of EST sequences.
- **Database of Single Nucleotide Polymorphism (dbSNP):** dbSNP collects >299 million reference SNPs from nine organisms.
- **ProtEST:** The ProtEST database provides precomputed BLAST alignments between protein sequences from certain model organisms and the six-frame translations of nucleotide sequences in UniGene.

Sequence-Based Database Query: BLAST

By far, the most commonly utilized DNA sequence search tool prevalent in the armory of a bioinformatician is the BLAST suite of algorithms. BLAST programs perform sequence-similarity searches against a variety of databases, returning a set of gapped sequence alignments. Within the NCBI tool set, the output from BLAST is linked to full database records. An alignment produced by BLAST is scored and assigned a quotient of statistical significance referred to as the expectation value (E-value), which also takes into account the amino acid composition of the query sequence. This composition-based statistical analysis, used in conventional protein BLAST searches as well as PSI-BLAST searches, tends to reduce the number of false-positive database hits. The BLAST output includes the standard pairwise alignment between the query and the sequence in the GenBank archive, as well as a best-hit similarity table. More recently, new features including a dendrogram that clusters sequence output according to distance from the initial query sequence have been implemented. Further, more advanced versions of BLAST, for example, MegaBLAST, have been introduced that not only handle batch submission of nucleotide sequences for analysis but also run ten times faster.

Genomics and Proteomics Databases

It has been reported that there are over 719 databases of both prokaryotic and eukaryotic contents containing both DNA and protein sequence data. Although this is a conservative estimate, this number increased by 171 databases from the previous year and is rapidly increasing in both number and global geographic distribution. The presence of genome sequence records in a repository is important for public accessibility of the information. However, the derived data, for example, protein sequence and function information, are essential for the exploration of biological meaning encoded in a genome sequence. As a consequence in addition to the genome sequence databases per se, there have arisen a number of protein sequence databases that utilize the vast amounts of genomic sequence produced. Some of the more established protein databases currently available are summarized in Table 2.

Table 2 Public protein sequence databases

<i>Protein sequence database</i>	<i>Organization</i>	<i>URL</i>
SwissProt	Swiss Institute of Bioinformatics (SIB)	www.expasy.org
PIR	Georgetown University, the United States	http://pir.georgetown.edu

UniProt	UniProt Consortium (EBI/SIB/PIR)	http://www.uniprot.org

PIR, Protein Information Resource; TrEMBL, Translation from EMBL; UniProt, a combination of SwissProt, TrEMBL, and PIR-PSD.

When additional information is added to a protein sequence, this increases greatly the value and integrity of the resource for database users. Thus, curated databases provide, in addition to the mere protein sequence entry, information that validates the biological function associated with the gene product. This phase involves the manual curation by expert biologists who validate and ensure that information coupled to the protein sequence is reliable. An appraisal of some of the more commonly utilized protein databases is described briefly in the succeeding text:

- **PIR:** Established in 1984, PIR is a large nonredundant protein sequence database that organizes proteins into related protein families and superfamilies with additional annotations based on functional, structural, genetic, and bibliographic data. The resource is extensively cross-referenced with DDBJ/EMBL/GenBank gene identifiers, comprising over 273 000 classified entries organized into more than 100 000 protein families and 36 000 super families.
- **SwissProt:** This is one of the leading curated, nonredundant protein databases in existence. It comprises over 548 000 curated sequence entries from over 8300 different organism species. Each SwissProt sequence entry is annotated by a biologist to ensure database integrity using scientific literature-based curation methods. This information is augmented by other physical (e.g., protein secondary and quaternary structure and protein domain architecture) and biological properties (e.g., posttranslational modifications and diseases associated with deficiencies) of the protein.
- **TrEMBL:** Translation from EMBL (TrEMBL) consists of computer-annotated protein sequence entries obtained from translation of all coding sequences (CDSs) in the DDBJ/EMBL/GenBank nucleotide sequence repositories. It comprises over 46 714 000 entries from over 62 000 different species of organism.
- **UniProt:** Developed by the US National Institutes of Health (NIH), this database combines the SwissProt, TrEMBL, and PIR resources. Launched in 2003, it is composed of three components: the UniProt Knowledgebase (contains SwissProt, TrEMBL, and PIR curated entries), UniProt Archive (UniParc) of newly loaded protein sequences, and UniProt nonredundant reference database. Sequence entries are cross-referenced to its component databases as well as to DDBJ/EMBL/GenBank sequence entries.

Over the course of the last decade, the nature of genome sequence databases has seen a restructuring and consolidation of their content from being merely repositories of sequence information to portals to analyze in detail the functions of genes and the biochemical pathways and cellular subsystem to which they belong. In addition, with the advent of higher-capacity genome sequencing centers with more powerful technologies, this has allowed for not only generation of more complete genome sequences but tools for supporting comparative genomics efforts (comparative genomics: the comparison of multiple whole genomes and their encoded genes based on DNA–DNA alignments to visualize gene order or synteny and chromosomal rearrangements). The increase of more integrated one-stop genome sequence databases providing access to whole-genome sequence, entire gene annotation sets and reannotation tools, pathway collections, and comparative genomics tools has required a development of a genome processing pipeline to handle the workflow. For example, given the presence of a particular genome DNA sequence, various operations need to be performed to make sense of the encoded information. Thus, an overview of aspects of this pipeline is helpful in appreciating the overall process involved in preparing and submitting a genome to a sequence database and analyzing the information contained therein. While all genome sequence databases do not necessarily treat the data in the same way, genome sequencing organizations in particular, since they are responsible primarily for generating the raw sequence data and making sense of it, need to address these major issues. Some of these aspects are outlined and elaborated upon in more detail in the succeeding text and include the following:

1. Identification of the coding regions or genes in the genome
2. Functional gene assignment or annotation
3. Association of gene functions with cellular and biochemical pathway databases

Identification of Coding Regions

Once a microbial genome is completed, it generally consists of a number of DNA contigs that represent the main chromosome(s) and any accompanying extrachromosomal plasmid sequences. Most prokaryotes comprise at least a single covalently closed, double-stranded DNA chromosome (Figure 1). Although the actual DNA sequence is paramount to understanding the behavior of the organism, the raw DNA sequence needs to be processed further to be of use to microbiologists. One of the first steps in this processing, for example, is the identification of the CDSs or ORFs in the genome. It should be noted that the genome does not need to be entirely complete to identify ORFs. In fact, many incomplete or draft genomes have ORFs identified and can provide very useful biological information. The heart of this process of ORF finding requires in principle an accurate recognition of those genomic sequences that are most likely to be protein (or RNA) encoding as well as a choice of suitable translation start and end points. A variety of alternatives exist in order to do this ranging from performing BLAST analyses to identifying DNA regions homologous to existing proteins, to utilizing a plethora of gene-finding algorithms. Even within the context of ORF finding, there are bioinformatics tool sets to identify protein-coding regions as well as those designed to find various noncoding RNAs, such as tRNAs and rRNAs, as well as more esoteric RNA molecules.

The computational identification of genes can be categorized into two distinct classes of algorithms, specifically intrinsic and extrinsic. Intrinsic gene finders use heuristics that make no explicit use of sequence homology information about DNAs or proteins outside the sequence under investigation. In contrast, extrinsic gene finders utilize information derived from sequence-similarity search methods to identify the locations of protein-coding regions. It is commonplace for gene finders of both types to be used in

unison in a gene-finding project, owing to their complementary nature. The identification of the exact gene start positions remains a challenging problem in gene finding, as many genes have relatively weak patterns indicating sites of translation and transcription initiation. Examples of some of the commonly employed gene identification programs used in genome projects include GeneMark, Glimmer (both examples of intrinsic gene callers), and CRITICA, an extrinsic tool that uses a comparative approach to identify coding sequences based on other identified coding regions. Once the coding regions of the DNA chromosome are identified, the DNA sequence of the identified ORFs is translated *in silico* using a standard microbial translation table that associates a codon to an amino acid entity. Thus, a cognate set of translated proteins can be derived from the set of deduced ORFs in a genome sequence. The next phase involves conferring functions, enzymatic or otherwise, to this set of predicted proteins encoded in the genome, a process referred to as gene annotation.

Gene Annotation

The process of microbial genome annotation generally refers to the steps involved in assigning biological meaning to the raw sequence data by identifying gene regions or functional features and determining their biological functions. As discussed earlier, identification of the coding regions is the precursor to the subsequent phase of finding the functions for the set of translated proteins. Functional gene annotation, that is, the process of predicting *in silico* the function of a specific gene product, is a combination of automated and manual methods that generate a connection between a coding sequence and its biological function. The automated phase of this process generally involves comparing the query sequence (protein) with a nonredundant database of all other proteins available using comparison metrics based upon extent of sequence similarity of the query and protein in the database and the associated biological function(s) of these best-hit protein similarity matches. Thus, this is a process based on a system of standardized transfer of functional annotations from curated databases of well-characterized proteins. The manual phase involves using various bioinformatics tool sets to impart a function to gene products that were not conferred an annotation after the automated round.

Tools for microbial genome annotation

Numerous bioinformatics approaches and tools exist that allow annotators to deduce manually the putative protein functions *in silico*. The logic associated with assigning a function to a protein is based on a number of criteria including the presence of published literature documenting direct experimentation identifying the function, occurrence of diagnostic protein domains associated with a function, extent of protein similarity to a known protein with a specific function, and chromosomal clustering of the cognate gene with genes of related function. An example of the latter might be the clustering of a putative tryptophan biosynthetic gene with other tryptophan biosynthetic genes in the *trp* operon. Some examples of publicly available resources that are useful to bioinformaticians for discerning biological functions associated with proteins are summarized in Table 3 and outlined in the succeeding text:

- Clusters of Orthologous Groups (COGs) of proteins: The database of COGs, maintained at NCBI, is composed of protein families encoded in completely sequenced genomes, representing the major taxonomic lineages. Each COG category consists of individual proteins or of protein families from at least three lineages that correspond to conserved domains. The COG database consists of over 138 000 proteins that form 4873 COG families contained in 66 genomes comprising 38 taxonomic orders, 28 classes, and 14 distinct phyla. The COG protein classification scheme is based on orthologous (ortholog: the functional equivalent of a gene/protein function between two genomes) relationships between functionally related proteins from different organisms.
- Pfam: The Pfam database is a curated collection of over 10 000 protein families. Each family is represented by two multiple sequence alignments and two profile hidden Markov model (HMM: a statistical model that attempts to find patterns or hidden parameters from observable parameters. HMMs have applications in many fields of pattern recognition, for instance, modeling protein families of related sequence (e.g., Pfam)) (profile HMMs). These alignments denote functional features conserved in the protein or domain. The Pfam protein domain families are themselves classified into related protein family groups or clans.

Table 3 Tools for gene annotation

Annotation tool	Functionality	URL
COGs	Functional families or related proteins	www.ncbi.nlm.nih.gov

MEROPS	Protease/peptidase database	http://merops.sanger.ac.uk
CAZy	Carbohydrate/glycoconjugate domains	http://www.cazy.org

- **InterPro:** The Integrated Resource of Protein Domains and Functional Sites (InterPro) is, as the name suggests, a protein family and protein motif database. It is an integration of several databases (e.g., Pfam, ProSite, and ProDom) that can be used to discern functional properties of protein secondary structures. The public InterPro database, maintained by the European Bioinformatics Institute (EBI), has processed over 384 000 proteins derived from SwissProt and TrEMBL through its annotation pipeline.
- **ProSite:** The ProSite resource is a pattern database describing protein domains, families, and functional sites; it contains currently 1308 patterns and 1112 profiles.
- **SignalP:** The identification of proteins that are exported or secreted from a bacterium is important to determine since they can affect pathogenic properties of microbes, for example. The SignalP resource, maintained by the Technical University of Denmark, is a tool that predicts the location of signal peptide cleavage sites in protein sequences from Gram-positive, Gram-negative, and eukaryotic organisms. Predictions are derived using techniques such as neural networks and HMMs.
- **Protein function-specific databases:** In addition to the burgeoning collection of protein family, domain, and motif databases that exist in the public domain, there are also a variety of resources focused on specific functional groups of proteins. Thus, for instance, the MEROPS database is a structure-based, curated resource for proteases, proteinases, and proteolytic enzymes containing over 66 500 sequences associated with 346 discrete enzymatic specificities. MEROPS derives its sequence data primarily from publicly available complete microbial genome sequences. Similarly, the Carbohydrate-Active enZymes database (CAZy) is a structure-based collection of catalytic and carbohydrate-binding protein domains of enzymes that degrade, modify, or create glycosidic bonds. The protein sequences present in these data are derived from the GenBank entries directly or from RefSeq. The information relating to carbohydrate and glycoconjugate breakdown and biosynthesis is gleaned from the genomes of 44 archaea, 501 bacteria, 25 eukaryotes, and 42 viruses.

Genome annotation databases

A variety of microbial whole-genome annotation databases, whether they are commercial, academic, or governmental in origin, have been developed over the recent years to handle the increasing volume of genomic data generated for public and commercial use. These databases provide resources to identify and annotate genes and their associated functions. This can be performed in an automated fashion, but also manual gene annotations can be conferred by users. Some of the more common genome annotation resources encountered are described briefly in the succeeding text:

- **Bioinformatics Resource Centers (BRCs):** BRCs are a group of five web-based research centers funded by US National Institute of Allergy and Infectious Diseases (NIAID). The five BRCs include Eukaryotic Pathogen Database Resources (EuPathDB), Influenza Research Database (IRD), PathoSystems Resource Integration Center (PATRIC) (for bacterial pathogens), Virus Pathogen Database and Analysis Resource (ViPR), and VectorBase (VB). These centers are intended to assist researchers to characterize various pathogens and generate drugs, vaccines, and diagnostic tools to combat them.
- **Integrated Microbial Genomes (IMG):** This data management system was created by the US Department of Energy (DoE) Joint Genome Institute (JGI) in 2005 to house and analyze the increasing volume of genomic data produced from DoE production sequencing facilities. The IMG platform provides public access to genome data from JGI sequencing projects. It contains genome, gene, function, and pathway information as well as visualization tools to compare genomes.
- **SEED annotation environment:** Developed through the US Department of Energy Argonne National Laboratory, the SEED annotation environment comprises 180 177 proteins with 213 distinct functional roles from 383 genomes.
- **Proprietary databases:** Genomics has been harnessed for the discovery of new genes, enzymes, and biochemical pathways. Consequently, the private sector has developed and exploited a variety of bioinformatics and genome analysis platforms to mine this wealth of genome data. An example of this is the subscription-based ERGO database created in 1998 to mine genomic information. This curated database comprises genomic data overlaid with gene, protein, and pathway information as well as metabolic reconstructions of entire genomes. Other commercial databases that exist are purely for corporate use and used for a variety of purposes ranging from data mining for novel enzymes to identification of drug targets in pathogenic microbes.

Integrating Genomics and Pathway Databases

As we have seen from earlier, the process of whole-genome sequencing and gene annotation can produce an extensive inventory of protein function assignments that can be propagated over a large set of sequenced genomes. With the improvement of both automated protein assignments and extensive manual tools to predict protein functions, an average bacterial genome can have between 50% and 65% of its protein complement assigned a discrete biological function. Some of these functions may participate in either metabolic (e.g., glucose dehydrogenase), nonmetabolic (e.g., DNA replication proteins), or regulatory (e.g., transcription factors) pathways. In turn, some of the protein functions, for instance, those with enzymatic roles, can be associated with their individual metabolic reactions and with each of its corresponding substrate and product metabolite compounds. Collections of enzymes, reactions, compounds, and pathways have been assembled and compiled from various sources through direct experimentation for over several decades. The fruits of this labor are available in published scientific journals. However, only recently as a direct consequence of genome sequence projects generating large quantities of predicted protein enzymatic functions have scientists connected the gene and protein information to pathway and reaction networks. This has led to the development of a more detailed understanding of the metabolic complexity inherent within a microorganism.

The integration of genome sequence with enzyme and pathway databases has attracted greater interest over recent years and led to a better characterization of microbial cell function. There are numerous applications of such integrated databases. This is of particular relevance to the biotechnology industry, for instance, where access to this information has a direct impact on the development of genetically engineered microbial strains that are capable of producing various compounds useful to society, including commodity and fine chemicals. Thus, for example, a detailed *in silico* metabolic network facilitates drug design for target enzymes in pathogenic microbes. Moreover, the availability of detailed reaction properties (e.g., thermodynamics and kinetics) aids the simulation of specific microbial pathway behavior to achieve a desired goal, exemplified by redirection of carbon flow to produce a useful metabolite.

Metabolic and cellular pathway databases are responsible for taking gene and protein sequences derived from genome sequencing projects and connecting them via their functional role(s) to a collection of individual compounds, reactions, pathways, and pathway networks (or subsystems). The ultimate goal of this information coupling is to generate a higher-level characterization of cellular metabolism and functionality than that obtained by looking merely at a gene inventory list. Examples of some of the enzyme and metabolic pathway databases under common use are summarized in Table 4. The strength of genome sequence databases leveraged with metabolic pathway content is a powerful scientific resource, and a description of some of these pathway databases and their content is merited.

- **BRAunschweig ENzyme Database (BRENDA):** The BRENDA database comprises information for metabolic enzymes and the molecules that bind them including potential enzyme inhibitors, as well as kinetic and thermodynamic data for the reactions. BRENDA comprises 3518 reactions with 47 630 associated compounds.
- **Kyoto Encyclopedia of Genes and Genomes (KEGG):** One of the most widely used public resources describing genes, functions, and metabolic reactions is KEGG, established in 1995 and maintained by the University of Kyoto, funded by the Japanese Ministry of Science. The database not only contains a large compound collection but also supports an extensive and ever-increasing collection of reactions and pathways, both metabolic and nonmetabolic. KEGG contains over 5473 reactions with 10 760 associated compounds in more than 200 pathways. The database is highly integrated with genomic data, compound, reaction, and pathway information. It is regularly updated with the latest publicly available complete genome sequences.
- **MetaCyc:** The goal of the curated MetaCyc database is to serve as an encyclopedia of metabolic enzymes and pathways. Maintained by SRI International (Menlo Park, California), it comprises a nonredundant collection of pathways that have been documented in the literature. MetaCyc contains 12 377 enzymatic reactions and over 11 900 compounds connected to 2310 pathways derived from over 500 reference genome sequences. Other derivatives of this database exist (e.g., EcoCyc) that comprise single organism (e.g., *Escherichia coli*) information repositories.
- **University of Minnesota Database of Biocatalysis and Biodegradation Database (UMBBD):** This resource is developed and maintained by the University of Minnesota (Minneapolis) and focuses on biodegradation pathways. It contains information regarding xenobiotic compound interconversions that are useful for industrial and bioremediation purposes.
- **Commercial metabolic pathway databases:** By far, the largest comprehensive commercial database, comprising both genomic and metabolic pathway data, is the ERGO database (Integrated Genomics, Chicago). It was developed from the Enzymes and Metabolic Pathways database (EMP) and Metabolic Pathways Database (MPW) but has expanded upon them to include 9506 reactions and 5978 pathways in >1000 complete and incomplete genomes. The resource integrates not only genomic data but also literature and high-throughput data (e.g., derived from whole-genome gene expression studies). Other databases are more specialized in nature, such as BioCarta that comprises pathways describing cellular signaling.

Many interaction pathway databases also exist (Table 5). Different from metabolic pathways, interaction pathways focus on the cellular signaling and regulatory reactions in cells. Besides KEGG, a brief introduction of these databases is discussed in the succeeding text:

- **BioCyc:** BioCyc is maintained by SRI International (Menlo Park, California). BioCyc collects 5500 pathway/genome databases and includes software tools to understand their data. BioCyc includes many derivatives, such as EcoCyc focused on *E. coli* and MetaCyc as described earlier.

PID	http://pid.nci.nih.gov
Reactome	http://www.reactome.org

- Pathway Interaction Database (PID): The PID is a freely available collection of manually curated and peer-reviewed pathways of human molecular signaling, regulatory, and cellular processes. This widely used database was created in a collaboration between the US National Cancer Institute (NCI) and Nature Publishing Group. PID contains 136 human pathways with 9248 interactions curated by NCI-Nature. It also imports 322 human pathways with 7575 interactions from BioCarta and Reactome. Although PID is widely used, the database has not been updated since September 2012.
- Reactome: This is a manually curated open data resource of human pathways and reactions. Currently, Reactome describes over 7000 human proteins, which participate in over 6700 reactions based on data extracted from over 15 000 research publications. The Reactome data resource links to other public resources such as the Gene Ontology (GO), UniProt, and ChEBI. User-friendly pathway analysis and visualization tools are also provided.
- Commercial interaction pathway databases and analysis tools: There are many commercial databases and tools to support interaction pathway studies. For example, BioCarta provides pathways describing cellular signaling, Ingenuity provides services and tools for variant and genomic data analysis, and Advaita Bioinformatics provides tools to support interaction pathway analysis.

Ontology-Based Gene and Omics Data Annotation

Biological/biomedical ontologies are sets of computer- and human-interpretable terms and relations that represent entities in the biological/biomedical world and how they relate to each other. Biomedical ontologies have emerged as a major tool for the integration and analysis of the large amounts of heterogeneous biological gene and omics data available in the postgenomics era. For example, the GO provides controlled and standardized terms for naming different types of biological processes, cellular components, and molecular functions. Creating such ontology-based annotations is highly valuable for both querying databases and analyzing high-throughput data. Since its first publication in 2000, GO has been cited by over 7000 peer-reviewed publications in PubMed and approximately 100 000 hits in Google Scholar. The Ontology of Genes and Genomes represents individual genes and genomes from different organisms. The Protein Ontology describes the relationships of proteins and protein evolutionary classes and delineates the multiple protein forms of a gene locus. The Ontology for Biomedical Investigations (OBI) has been used for representation of a wide range of investigations. The Vaccine Ontology has been used in different applications such as vaccine data integration and literature mining. Formatted based on the Web Ontology Language (OWL) technologies, these ontologies are being more and more widely used for a variety of biological and biomedical applications.

New Directions: Metagenomics

Genome sequencing of environmental samples or microbial communities, referred to as metagenomics, is the genomic analysis of organisms by direct extraction and cloning of DNA from an assemblage of microorganisms. This is in contrast to more conventional individual whole-genome projects where the genetic material from one organism is sequenced completely. The rationale underlying metagenomics arose from evidence (e.g., 16S rRNA gene sequence analysis) that as yet uncultured microorganisms represent the vast majority of organisms in most environmental niches. In many environments, approximately 99% of the microorganisms cannot be cultured by standard techniques. Although analysis of 16S ribosomal RNA genes provided only a phylogenetic description of community association, metagenomics facilitates study of the genetic diversity, physiology, and ecology of environmental microorganisms. The discovery of new genes and proteins identified through metagenomics approaches includes the first bacteriorhodopsin of bacterial origin, novel small molecules with antimicrobial activity, and antibiotic resistance determinants. The assembly of multiple genomes in an environmental sampling, for instance, has also provided insight into energy cycling within the community, genome structure, gene function, population genetics, and lateral gene transfer among members of an uncultured community.

The workflow for a metagenomics project is not dissimilar to conventional whole-genome projects, except that DNA is prepared from an assemblage of organisms rather than a single one. Libraries of genomic DNA fragments are then cloned into a standard vector (e.g., fosmids and bacterial artificial chromosomes (BACs)) and transformed in an *E. coli* bacterial host strain. Clones isolated from the bacterial plasmid library are then 'shotgun' sequenced on both strands of the insert DNA, that is, everything that has been cloned into the vector is sequenced in this way. The sequenced DNAs are then assembled in to larger DNA fragments, and this set of

DNA sequences can then be compared against databases of known sequences using BLAST algorithms or similar sequence analysis tools. The broad taxonomic category of the best BLAST hits can be utilized, for instance, using NCBI taxonomy, to provide some notion of which taxonomic clade the DNA sequence sample fragment may have originated from. Metagenomics sequencing projects have been performed on a number of environmental isolates including ocean water from the Sargasso Sea, human intestinal microflora, and heavy metal-contaminated effluent water from mining projects. The sampling of such genome sequence data sets is also beneficial from an industrial perspective and has been exploited to discover and clone new genes associated with novel enzymatic properties. The volume of large metagenome sequence submissions to GenBank and other public sequence repositories is beginning to increase rapidly as sequencing technologies improve and the tools to assemble and analyze these sequences become available.

Glossary

Assembler A computer program that pieces together overlapping reads to reconstruct the original sequence.

Captured gap (a sequence gap) Unsequenced area between two contigs spanned by at least one subclone or sequenced fragment

Contig 'A set of gel readings that are related to one another by overlap of their sequences. All gel readings belong to one and only one contig, and each contig contains at least one gel reading. The gel readings in a contig can be summed to form a contiguous consensus sequence and the length of this sequence is the length of the contig'.

Finishing The process of improving a draft assembly composed of shotgun sequencing reads, resolving misassembled regions, closing sequence gaps, and validating low-quality regions to produce a highly accurate finished DNA sequence (<1 error in 10 000 bp).

Gap Unsequenced area between two contigs.

Paired (sister) reads Sequences generated from both ends of a DNA fragment. Such reads are oriented toward each other and the distance between them is equal to the template length.

Quality score The probability of a wrong basecall. A Phrap quality score of X corresponds to an error probability of approximately $10^{-X/10}$ (a score of 30 means that the error probability is 1/1000 or 99.9% accuracy for a base in the assembled sequence).

Read Gel reading generated during the DNA sequence process.

Repeats Sequences of varying lengths found in multiple copies in the genome.

Scaffold A group of ordered and oriented contigs.

Sequencing by Synthesis (SBS) A sequencing approach that involves multiple parallel microsequencing addition events occurring on a surface, where data from each round is detected by imaging.

SNP Single-nucleotide polymorphism.

Uncaptured (physical gap) Unsequenced area between two contigs with no subclones or sequenced fragment spanning it.

Abbreviation

AMOS	A Modular Open-Source
BAC	Bacterial artificial chromosome
EMBL/ENSEMBL	European Molecular Biology Laboratory
GAP	Genome Assembly Program
GEBA	Genomic Encyclopedia for the Bacteria and Archaea
LLR	Log-likelihood Ratio
NHGRI	National Human Genome Research Institute
NGS	next generation sequencing
PCAP	Parallel contig Assembly program
PCR	Polymerase Chain Reaction
SBS	sequencing by synthesis
SNP	single-nucleotide polymorphism
SPAdes	St. Petersburg genome assembler
SPS	Southwest Parallel Software
SSAKE	Short Sequence Assembly by progressive K -mer search and 3' read Extension
TEM	transmission electron microscope
WGS	Whole-Genome Shotgun
YAC	yeast artificial chromosome

[☆]*Change History:* August 2014. A Lapidus introduced small changes into the Abstract to make it current, updated keywords and special terms, significantly updated sections 'DNA sequencing', 'Sequencing strategies', 'Libraries', 'Pre-Processing of raw Data', 'Assemblers', 'Algorithms for Second-generation Sequencing Data Assembly', 'Assembly of Metagenome Shotgun Sequences', 'Genome Assembly Improvement and Finishing', 'NCBI Trace and Assembly Archives' Updated sections 'Further Reading', 'Relevant Websites' Renamed and slightly updated section 'Microbial Genome project' (now it is 'Genome project'). Significantly updated Table 1. Added new Table 2. Added new sections 'Single-cell genome assembly', 'Third-Generation Sequencing and Genome Finishing', 'Assessing quality of draft genome assembly'. Created section 'References'.

This article is an update of A.L. Lapidus, Genome Sequence Databases: Sequencing and Assembly, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 196–210.

Defining Statement

Putting together data produced during the sequencing stage of a genomic project is comparable to solving a complicated puzzle made of several million pieces. Thanks to the combined efforts of enthusiastic software developers and biologists studying genome structure and functionality, a number of successful algorithms and approaches for genome assembly have been created. High-quality genomic assembly lays a solid foundation for functional genome analysis.

DNA Sequencing

The knowledge of the particular order of nucleotide bases of genomic DNA is widely used both in fundamental biological research and in many applications. This information plays a significant role in medical and forensic studies and is of great value for the pharmaceutical industry.

The era of DNA sequencing began about 30 years ago, when two methods of primary DNA structure determination appeared almost simultaneously. One of them was developed by A. Maxam and W. Gilbert at Harvard University and was based on the use of chemical modifications of DNA. The other method was published by F. Sanger and A. Coulson from Cambridge and is called the chain-termination method. Since then significant changes have been introduced both in the Sanger method (which has been completely automated and therefore has found wider application than Gilbert's method) and in a variety of other sequencing technologies.

Modern approaches are aimed at significantly reducing the costs associated with sequence determination. In 2004, the National Human Genome Research Institute (NHGRI) set a task for the global scientific community to lower the cost of sequencing of an individual human genome to \$1000, with an intermediate goal being to reduce the cost of sequencing a mammalian-sized genome to \$100 000. In January 2014 this goal –a whole human genome at a cost of \$1000 –was achieved by launching the HiSeq XTen sequencing system]. This low price allows using DNA sequencing not only in research, but in clinical diagnostics, pharmaceuticals, forensics, ecology etc. to simultaneously analyze the entire set of genes within an organism as well as between species and individuals.

The NHGRI initiative resulted in rapid proliferation of next generation sequencing technologies (NGS) including pyrosequencing, base-by-base sequencing by synthesis (SBS), sequencing by ligation, nanopore sequencing, and single-molecule sequencing by synthesis in real time. These newest technologies are currently at different stages of development and implementation.

As compared with the traditional Sanger sequencing, the greatest advantage of the first three NGS approaches is very high level of parallelization, as they are capable of performing up to 10^7 reactions in one experiment. In addition, the tiny volume of the individual wells (picoliters) in which sequencing reactions are running, and high data density (10 000 times higher, than in case of the latest microelectrophoresis-based capillary instruments) significantly decreases the volume of reagents necessary to perform the reactions. Another positive aspect of the new methods is the ability to circumvent the step of DNA cloning and propagation in *Escherichia coli* cells, thus avoiding the problems of biased genome coverage due to the presence of genomic areas, which are hard or even impossible to clone in *E. coli* (so called unclonable areas). The downside of the first NGS technologies, as compared with the Sanger approach, is the length of the reads produced. The 454 Genome Sequencer 20 System instrument (the first commercial NGS platform) produced reads of about 110 bp, although the read length has increased up to 1 kb with the latest GS FLX Titanium chemistry. Meanwhile, technologies using SBS and sequencing by ligation (Applied Biosystem SOLiD; polony-based approaches) produce reads of 25–50 bp long. Such short reads impose certain restrictions on the use of new technologies: whereas 454 sequencing has been successfully applied to *de novo* genome sequencing resulting in a gapped assembly with an error rate of about 1/3000–1/5000 bp, the ultrashort reads produced by Solexa technology however appear to be useful for resequencing purposes only, when a high-quality reference sequence is available for alignment. The use of 25–50 bp reads for *de novo* genome sequencing appears to be very problematic.

After being acquired by Illumina, Solexa became known as Illumina. This technology uses the SBS sequencing approach to provide massively parallel sequencing and detects single bases as they are incorporated into growing DNA strands. Read length varies from 100 to 250 bp depending on the sequencing instrument used (MiSeq, HiSeq 2000, HiSeq2500). Low error rate of Illumina reads ($\leq 0.1\%$) makes this sequencing technology very attractive for a number of applications including *de novo* genome assembly.

Ion Torrent is yet another NGS approach. It uses semiconductor sequencing technology of SBS. The Ion PGM sequencer detects changes in pH when a nucleotide is incorporated into the DNA molecules and a proton is released. This technology produces reads of 400 bp long with about 1% error rate allowing single nucleotide polymorphism (SNP) detection as well as whole genome assembly.

Among the numerous methods on the drawing board, special attention should be given to real-time sequencing of DNA molecules. Such methods use very small amounts of genomic DNA and require supersensitive detection methods. The success of these methods critically depends on the quality of genomic DNA used in the experiment, because any damage to DNA in the process of its isolation would result in corrupted sequence. Theoretically, the read length produced by this type of technology is equal to that of a full genome.

MacBio (SMRT) sequencing is one of the first real-time single-molecule sequencing techniques that generates long reads (10–15 Kb) without requiring an amplification steps and has the unique ability to distinguish methylated bases from normal nucleotides. This feature gives the possibility of studying the epigenetic potential of different organisms. Read error rate is high, but errors are random and thus can be corrected via increased coverage. Long reads play a crucial role in the gap closing step of the whole genome assembly and PacBio gave genome finishing, a step that for several years was set aside as time-consuming and not cost efficient, a much needed boost.

A number of development teams have used nanopores or an electron microscope for signal detection. When nanopore-based detection is used, DNA moves through 1.5-nm-wide pores in an electric field and a detector measures the change in conductance within the pore. ZS Genetics, Inc. was working on a single-molecule sequencing method, which uses a single-stranded DNA molecule to form a complementary strand via the incorporation of labeled nucleotides, thus making the DNA molecule visible under a transmission electron microscope (TEM). The company claims that their system is capable of sequencing DNA strands of 20 000 bp or longer.

The UK company Oxford Nanopore Technologies is developing a new generation of nanopore-based sequencing approach. The MinION system allows producing long reads up to 10 000 bases long. The current error rate is about 4% and it was observed that technology produces systematic sequencing errors, which is more challenging to correct bioinformatically than random ones.

The list of companies and university-based groups of researchers working on improving sequencing technology goes on. Some of them have already become commercially successful; others are still only approaching this goal, whereas some already failed or will fail (Table 1). In many cases a combination of different sequencing approaches allows to produce high-quality sequence fairly quickly and at very low cost.

Genome Project

The process of decoding a genome is a complex scientific task composed of complete genome sequence determination and functional analysis of the genes of the organism being sequenced. Thus each genomic project consists of sequencing, assembly, and annotation stages.

When starting a project, it is useful to estimate the size of the genome, its GC content, number of chromosomes (even some microbial cells contain more than one chromosome), and potential presence of plasmids (circular or linear extra chromosomal elements) in case of microbial projects. Choosing the most appropriate sequencing and assembly strategy is as important as deciding which tool to use for the subsequent functional analysis of the genome.

Table 1 Companies involved in DNA sequencing technology development

Company names	Throughput	Read length (bp)	Approach	Application	Web site addresses
Solexa/Illumina MiSeq HiSeq 2500 NextSeq 500	0.3–15 GB/5–6 h 10–1000 GB/ 7 h–6 days 20–120 GB/ 12–30 h	2×300 2×125 2×150	Sequencing by synthesis (SBS)	Whole microbial genomes, Resequencing expression profiling, RNA-seq, targeted sequencing	http://www.illumina.com

Sequencing Strategies

Three sequencing strategies have been used in genomic projects sequenced using Sanger technology. The first one is based on the use of ordered collections of overlapping BAC (bacterial artificial chromosome) or YAC (yeast artificial chromosome) clones. To follow this approach, one should make a large-insert library (BAC, YAC), map clones to the genome using fingerprinting or hybridization, pick the minimal set of clones covering the entire genome, and sequence and assemble each clone from this set separately. This strategy appeared to be very labor-intensive and is not widely used today.

In 1995 the Whole-Genome Shotgun (WGS) sequencing approach was introduced and it quickly became the most popular strategy for microbial genome sequencing. According to this strategy, each sequencing project requires genomic DNA (gDNA) isolation, library construction, sequencing of the subclones, assembly of sequenced data, and genome finishing (Figure 1).

For the project to succeed, it is vital to begin with high molecular weight gDNA, which makes possible the creation of three genomic libraries with different insert length. Typically, the insert sizes are set at 3, 8, and 40 kb, thus creating 3-kb, 8-kb and fosmid DNA libraries. Library inserts are then sequenced from both ends, resulting in approximately 8–9X genome coverage with paired reads. Reads are aligned against each other by using various genome assemblers to produce a draft assembly, which consists of contigs linked into larger scaffolds based on the information about read pairs. The genome closure stage (finishing) is used to solve all possible misassemblies within contigs and to close gaps in (sequencing or captured gaps) and between (physical or uncaptured gaps) scaffolds to build a single high-quality contig spanning the entire genome (note that final assembly might contain more than one contig if the genome consists of a larger number of replicons).

Before moving on to a more detailed description of the WGS assembly and finishing stages, it is necessary to mention that new sequencing technologies gave birth to a third sequencing strategy. In many cases this is a combined approach that uses sequencing data produced by different sequencing platforms. The combined approach has its own advantages and drawbacks (which will be discussed later on), but seems to be promising considering it has the potential to speed up the completion of genome projects and lower their costs.

Libraries

WGS sequencing begins with random shearing of gDNA and used to continue with further cloning of small fragments of DNA into different cloning vectors. Depending on vector capacity to accept foreign DNA fragments of different length, small- or large-insert genomic libraries can be created. Libraries of different insert size play different roles in the genome assembly: whereas small-insert clones (3 kb on average) are needed to obtain the necessary genome coverage, larger insert libraries (8 kb, cosmids, fosmids, or BACs) serve to verify the accuracy of contig assembly and to order and orient them.

When dealing with small-insert libraries, it is important to be certain that each vector contains only one insertion. Simultaneous cloning of several random DNA fragments will lead to chimeric clones and thus will cause problems for the later stages of genome assembly. A number of approaches, such as vector/insertion ratio optimization in the cloning ligation reaction, efficient size selection, and the use of specially designed vectors allow minimization of the probability of multiple fragment co-cloning.

Large-insert libraries are usually created by cloning DNA fragments of 25–200 kb into cosmid, fosmid, or BAC vectors. In addition to the fact that such vectors can carry long fragments of foreign DNA, they are present in one or two copies in *E. coli* cells (low copy number vs. high copy number vectors used for 3- and 8-kb libraries). Low-copy-number vectors are very useful when so-called poisonous sequences (i.e., sequences whose presence or expression interferes with the biology of the host organism in some way resulting in host death) are cloned. Mechanisms of toxicity differ; they include cases of open reading frames that code for toxic proteins, operators that reduce effective concentration of an essential DNA-binding regulator, certain (AT)-rich DNA fragments, which can serve as strong promoters in *E. coli* and initiate transcription of genes encoded by the vector itself at a very high level. It has been shown, for example, that some membrane and ribosomal proteins are toxic for *E. coli* cells when highly expressed. This has been confirmed by numerous experimental observations that some areas of bacterial genomes are represented only by large-insert clones.

The next step is to sequence the inserts from the clone libraries. The WGS strategy does not mean that a complete sequence of the entire insert cloned into the vector will be produced. Typically, inserts are sequenced from both ends resulting in two sequencing reads of about 700 bp each. These pairs of reads, otherwise known as sister reads, form a mate pair. The sister reads are oriented toward each other. The distance between them is within the mean library insert size plus or minus three times the standard deviation of the insert size. When assembled (see below) sister reads may appear in the same or a different contig. Information about mate-paired reads is a very important input for assembly tools (assemblers).

If we assume that the library clones (subclones) cover the chromosome evenly (i.e., there is no cloning bias) and that the length of each read is approximately 700 bp, sequencing of 715 clones will be needed to cover ($1 \times$ read coverage) a 1-MB bacterial genome once. To obtain $1 \times$ clone coverage of the same 1-MB genome one needs to have 333 clones from the 3-kb library or 125 clones from

Fig. 1 Whole-Genome Shotgun sequencing steps.

Fig. 2 Read and clone coverage.

the 8-kb library. In practice, clones are not randomly distributed and some areas remain unsequenced (gaps) even if $8 \times$ read coverage is provided (Figure 2).

Most library preparation procedures for current NGS platforms consist of (i) a DNA fragmentation step performed by using physical, enzymatic or chemical methods, (ii) a DNA repair and end-polishing step followed by (iii) a platform-specific adaptor ligation. The PCR amplification step (iv) helps to produce enough DNA for further sequencing. As a result millions of small DNA fragments become available for sequencing in multiple parallel reactions. With minor differences these steps are used in library preparations protocols by major NGS platforms developed by 454/Roche, Solexa/Illumina, Thermo Fisher Scientific (SOLiD and Ion Torrent) and Pacific Biosciences (PCR amplification is not required).

High quality NGS libraries depend significantly on the amount and the quality of the DNA source material as well as the method used for DNA isolation. The term 'quality' is interpreted differently depending on the expected application (whole genome sequencing, genome re-sequencing, targeted sequencing, etc) (Chain et al., 2009).

Most of the existing NGS platforms produce paired-end or/and mate pair libraries allowing sequencing of DNA fragments from both ends. The distance between paired reads is called an insert size and is a critical parameter for subsequent genome assembly. A combination of several paired libraries with different insert sizes is needed to be able to resolve repeats of various lengths and nature. Requirements for the optimal insert size combination is dictated by genome features and do not differ from the ones used in Sanger libraries. While some NGS platforms do not support large insert size library creation, others like 454/Roche produced up to 20 kb libraries.

The recently emerged single-cell sequencing approach utilizes whole genome amplification with Multiple Displacement Amplification (MDA) (Lasken, 2009) to generate enough amplified gDNA to construct sequencing libraries. Single-cell libraries suffer from considerable bias, caused by nonlinear amplification and single-cell data demonstrates a highly non-uniform coverage, high rate of chimeric reads/read-pairs and a large number of sequencing errors. These properties of the sequencing data tend to further complicate genome assembly.

Assembly

Pre-Processing of Raw Data

The next step of the WGS project is to assemble the DNA reads produced during the sequencing stage to reconstruct the entire genome. The assembly of tens of thousands of reads into a few contigs (preferably into one for each replicon – the ultimate goal of any sequencing project) is a very complicated computational task. So, what makes the whole genome assembly so challenging?

Sequenced reads are never 100% error-free. Physical limitations of the gel electrophoresis technique, chemical artifacts, and human mistakes contribute significantly to assembly complications. The second equally or even more important factor further complicating the assembly is the presence of areas of identical or nearly identical sequence (repeats) in DNA molecules. Even the best assemblies contain gaps and imperfections due to genome complexity, sequencing biases, repeats and polymorphism, data and algorithm limitations.

A number of software tools were developed to address these issues with Sanger reads. Computer programs like ABI-basecaller, pregap4, and Phred analyze raw data produced by the automated DNA sequencing machines by converting them into a sequence of bases (basecalling) and assigning quality scores to each nucleotide. Because of its high accuracy, the Phred basecaller became the most widely used tool. Phred quality scores range from 4 to about 60 and define the probability that the base call is correct. A base with a quality score of 20 or higher is usually considered a high-quality base. 'Phred20' score means that the probability of the base being called incorrectly is 1 in 100. Quality at the beginning of the Sanger read and closer to its end is lower than in the middle of the read. This means that the error rate is higher (sometimes significantly) toward the end of the read, which makes assembly more difficult. (The same trend is observed for reads produced by Illumina sequencers).

The gold standard Sanger reads of about 1000 bp long have currently an error rate as low as 10^{-5} error per base (Shendure and Ji, 2008). The so called second generation sequencing (SGS) technologies (SOLiD, 454, Illumina, Ion torrent), while faster and cheaper, produce shorter reads of a lower accuracy compared to Sanger sequencing. Having a lot in common, these technologies use different reagents and signal detection systems, which leads to different types of errors made during sequencing. Some read errors can be corrected by increasing sequence coverage, but this will again raise the sequencing cost. More accurate base-calling allows decreasing the amount of coverage needed to reach the desired level of accuracy and therefore decreases the overall cost of sequencing.

Illumina provides its own base caller Bustard that creates a model from the raw intensities and performs base calling based on the produced model. Alta-Cyclic (Erlich et al., 2008) was developed to improve Illumina base calling. It uses machine learning to minimize noise factors, systematic biases and allows producing longer reads of a better quality. BayesCall, another model-based (a fully parametric model) base calling tool, 'improves Bustard's average per-base error rate by ~51%' (Kao et al., 2009). Ibis (Improved base identification system) (Kircher et al., 2009) is yet another base caller for the Illumina sequencing system. It incorporates both sequencing errors and neighboring signals into its statistical learning procedure. Further improvement of this tool called freeIbis (Renaud et al., 2013) represents an open source version of Ibis that requires less processing time and computational resources.

Errors in 454 reads are caused by mixed clusters, incomplete synthesis of the complementary DNA strand, possible incorporation of multiple different bases, and presence of consecutive runs of the same base (homopolymers). It was observed that the native 454 base caller underestimates the actual base accuracy assigning Q30 quality score to about 25% of bases produced. A base calling program, Pyrobayes (Quinlan et al., 2008), was developed to produce more accurate higher quality base calling. These and other base-callers for Illumina and 454 sequencing platforms are described in more detail in (Shendure and Ji, 2008).

New algorithms were also proposed and thus new programs were developed to convert Ion Torrent (pyrosequencing-like sequencing platform) flowgrams into reads. FlowgramFixer uses 'a linear-time method that combines a state machine with a Viterbi algorithm to find the nucleotide sequence that maximizes the likelihood of the observed flowgram' (Golan and Medvedev, 2013). The developed algorithm is applicable to any flowgram-based sequencing platform.

The error correction step for IonTorrent sequencing reads requires special attention. Existing approaches assume that most sequencing errors in the NGS data are mismatches, while in IonTorrent reads (similar to 454) homopolymer indels are most prevalent. Recently developed IonHammer introduces several novel algorithms based on homopolymer-space Hamming graph clustering and corrects both mismatches and indels. IonHammer has been shown to significantly reduce the average error rate (about eightfold), which is crucial for de novo assembly applications.

In order to be able to develop an error correcting tool one must be familiar with the different errors associated with the different sequencing platforms, which in turn makes it very important for downstream data analysis.

Another group of computer programs (available both as independent tools and as part of larger assembly packages) was developed to mark (pregap4 – part of the Staden package or trim out (Lucy, Arachne trimming module, MAGIC-SPP) low-quality tails of the reads and to mask or remove cloning vector sequences (Cross-Match provided by Phrap; vector_clip (Staden package-gap4), Lucy, and so on), mostly found in the beginning of the reads but also occasionally detected at the end of the read if the insert is very short.

Instead of vector sequence, NGS reads frequently contain adapter sequence in both the 5' and 3' ends of the read, which is also caused by the fact that the reads are longer than the insertions. If not trimmed, these sequences will create confusion during downstream assembly. This problem is very well known in relation to the Nextera library sequenced with 250 pb reads.

In contrast with the Sanger libraries, when the sequence of the cloning site is known and thus the exact start and/or end of the inserted gDNA fragment can be defined, it is not always easy to recognize the adapter especially if the sequence at the end of the read is of poor quality. To address this and other pre-processing problems new NGS tools were developed. Their goal is to recognize adapter sequences, perform read trimming and quality filtering (Trimmomatic, AdapterRemoval, Cutadapt, FASTX, Trim Galore!). Such preassembly data treatment significantly improves assemblers' performance and increases assembly quality.

Assemblers

Despite all the efforts high quality genome assembly is a complex task that so far remains unsolved. It is well known that majority of problems caused by repeats present in all genomes of any nature. The usage of multiple methods of genomic DNA isolation, different sequencing technologies and different types of genomic libraries for research projects introduces additional levels of complication to the genome assembly.

Generally speaking, most long reads Sanger assemblers follow a three-phase approach: overlap, layout, and consensus (OLC). During the first phase, the assembler determines which pairs of reads overlap; these reads may have been drawn from the same DNA region. During the layout phase, the assembler places the reads, thereby attempting to reconstruct contiguous sequences of DNA, or contigs, and to order and orient contigs to build scaffolds. During the final phase, the assembler uses the reads that have been placed in order to generate the consensus sequence – the assembler's best reconstruction of the original DNA sequence. Advanced algorithms employed by modern assemblers are also able to address such important problems as repeat locations and at least their partial resolution and identification of chimerical reads.

The first assembler was described by Roger Staden and has been significantly improved over the following few years. The current version of this assembler – GAP4 (Genome Assembly Program) – 'contains all the tools that would be expected from an assembly program plus many unique features and a very easily used interface'.

One of the most commonly used OLC assembly programs is Phrap. To detect overlaps, Phrap scans the set of reads to find pairs with perfectly matching subsequences and passes these sequences to a banded Smith–Waterman algorithm to find the optimal local alignment. Read couples that are near-duplicates are retained, while combined read couples that do not have good matching segments are considered to be not a match and are discarded. The Log-likelihood Ratio (LLR) score, a combined measure of match length and quality, is computed for each retained match. In the layout phase, Phrap constructs contig layouts using matches in decreasing order of LLR score. Version 3 of this assembler does not use paired read constraints and does not generate scaffold

information. A separate program, such as Bambus, may be used to order and orient contigs. Phrap 4 (also known as Southwest Parallel Software (SPS) Phrap) is an updated version of Phrap which, unlike Phrap 3, uses paired reads information and produces fewer misassemblies. Phrap 4 can create scaffold information using mate pair links, with an option to link contigs only if two mate pairs from the same library link the two contigs. Phrap 4 can also be instructed to ignore singleton mate pairs in the assembly. For consensus sequence generation Phrap analyses all individual reads and picks bases with the highest Phred quality score. Phrap is one of the best tools for working with low-quality reads and for assembling low-coverage nonrepetitive regions. The latest version of this assembler provides some support for next-generation sequencing reads.

Another widely used assembler is Arachne. To perform the overlapping stage, Arachne finds all reads that share a k -mer, an identical sequence of k bases (word), but excludes (masks) the reads that occur with extremely high frequency. In practice $k = 24$ is used. This exclusion improves the efficiency of overlap detection, and is thought to exclude high-fidelity repeat sequences. For layout, Arachne finds pairs of paired reads with sequence overlaps at both ends. Arachne iteratively identifies and extends 'paired pairs', forming minicontigs, and then assembles true contigs by avoiding assembling across repeat boundaries. Some of these contigs will represent repeat regions (they are identified by high depth of coverage, and by conflicting mate pair links to other contigs). The nonrepeat contigs are organized into scaffolds if they are linked by at least two mate pair links; priority is given to contigs that are separated by short distances and spanned by many mate pair links. Arachne then attempts to fill in the gaps between contigs by finding a path of repeat contigs across each gap, guided by mate pair links. The improved versions of Arachne first construct a set of contigs that are unlikely to include a misassembly, and then iteratively improving the initial assembly through read placement and contig breaking at suspicious points. Arachne is quite efficient at repeat resolution, with the exception of tandem repeats. To build the consensus sequence Arachne converts pairwise alignments of reads into multiple alignments and merges overlapping adjacent contigs in scaffolds. Quality scores are used to create and evaluate read alignments. This very powerful assembler was also successfully used for mammalian genome assembly.

Parallel Contig Assembly Program (PCAP) uses a parallelized local alignment technique and length of the word (k) of 12. For layout, pairs of reads are placed in order of decreasing local alignment score. The quality of the current layout is then determined by checking mate pair constraints. Corrections are made to the region with the largest number of constraint violations. The process of constraint assessment and correction is repeated until no areas with constraint problems are found. Finally, the assembler attempts to close gaps between linked contigs using the reads overlapping the ends of the contigs together with reads considered to lie in repetitive regions. PCAP computes a consensus sequence for contigs based on an alignment of reads in contigs and uses both quality values and coverage information for each base. The latest version of this assembler PCAP.REP does not use the constant word length to overlap reads. The developers implemented the idea of using superwords for more effective overlapping of repetitive reads. Superwords consist of more than one k -mer and can be of different length. It was demonstrated that the new method of overlap detection is very efficient in both unique and repetitive regions and that PCAP.REP produces more accurate and contiguous assemblies of whole-genome data sets.

The AMOS Comparative assembler (AMOS-Cmp, A modular, open-source whole genome assembler) skips the overlap step. It aligns reads of the target genome to the reference genome of a closely related organism by using a modified version of the MUMmer algorithm. Authors call this approach alignment–layout–consensus, since the assembler produces consensus from the alignment. However, even closely related organisms can significantly differ from each other due to insertions, deletions, rearrangements, repetitive regions and lateral gene transfer thus making comparative assembly challenging. The AMOS-Cmp is aimed to overcome these problems. Taking into consideration the increasing number of high-quality completed reference genomes in public depositories, the comparative (assisted) assembly approach has a bright future.

Algorithms for Second-Generation Sequencing Data Assembly

As was already mentioned above, second generation sequencing technologies produce short or ultra short reads (35–200 bp) and the number of reads for a given genomic project is significantly higher than what is obtained in the case of the Sanger method. This makes usage of the previously described assembly tools nearly impossible. Another problem with using traditional assemblers in connection with next-generation sequencing technologies is the fact that each of these platforms generates data in different formats (flowgrams, images, text format (fasta), and so on) and that these formats differ from the one generated by Sanger sequencers. As a result, there was an urgent need for new computational methods for analyzing massive amounts of very short reads and for managing this overwhelming volume of data. In response to this need new algorithms have been created to analyze short reads in a number of applications, including *de novo* genome assembly and visualization, polymorphism detection, gene expression, metagenomics and single-cell analysis.

The first short-read sequence assembler was described in a publication by EULER assembler developers (Pevzner et al., 2001). A modified version of EULER was used to assemble simulated reads of length 80–200 bp created to obtain $30 \times$ coverage for several test cases (BACs and viral and bacterial genomes). The same main problems – repeats and sequencing errors – complicate short-read assembly, but shorter reads result in a larger number of repeats, which creates additional difficulties for assembly tools (repeats that are shorter than the read length). The EULER assembly approach, which performs fragment assembly by finding an Eulerian path through a de Bruijn graph representation of a genome, works well on error-free reads. To avoid or minimize the influence of the error rate, the modified version of EULER addresses the problem of errors by correcting them prior to assembly, thus eliminating alignment and basecalling steps. However, to adapt to variations of error rates and types in second generation sequencing methods, the corrective stage needs to be optimized. Experiments with the EULER assembler allowed assembly of short reads into relatively

long contigs and thus demonstrated the feasibility of such assembly for *de novo* draft sequencing. It was also predicted that significant finishing efforts would be required to resolve repeats and misassemblies to produce the finished genome.

454 Life Science company (Roche) has developed its own *de novo* flow-space assembler optimized for an increased number of 80–120 bp flow-based reads. The assembler, Newbler (Margulies et al., 2005), consists of three modules performing the overlap-layout-consensus operations and uses only high-quality flowgrams for better performance (it is stated that quality scores used by Newbler are in good correlation with phred scores). Errors most typical for the 454 platform are the ones related to homopolymers. They are caused by over- or underestimation of the intensity of the signal or by their combination.

To overlap reads the Overlapper module compares all flowgrams by using a hashing indexing method. The next module, Unitigger, groups the overlapped reads into ‘unitigs’. As defined (Margulies et al., 2005) ‘a unitig’ is a collection of reads whose overlaps between each other are consistent and uncontested by reads external to the unitig. Unitigs are constructed from consistent chains of maximal depth overlaps’. Created unitigs then go through the all-against-all comparison to join the overlapping ones and to break the contigs at the repeat boundaries (Multialigner). For high-quality consensus generation the Newbler assembler averages the signals for each individual assembly position. This assembler was first tested on several microbial genome assemblies and is currently employed by all laboratories where 454 instruments are being used.

The latest versions Newbler is capable of assembling not only 454 data, but Ion Torrent PGM and Proton reads ((IonTorrent/Thermo Fisher Scientific) since these instruments produce a similar type of data (Table 2). This is one of the few programs that can handle data from multiple technologies to perform hybrid assembly and *de novo* assemble genomes up to 3 Gb in size using mate pair libraries with 3, 8, or 20 kb insert size in addition to paired end data. Newbler can also be used for assembling transcriptome data. To do so, it first collects reads into Isogroups, and then creates Isotigs out of those groups.

SSAKE (the Short Sequence Assembly by progressive *k*-mer search and 3’ read Extension) program was developed in an attempt to achieve the goal of *de novo* genome assembly using 25-bp reads. Simulated error-free data sets created for bacteriophage (PhiX174), SARS virus (SARS TOR2), bacterial (*Haemophilus influenzae*), and metagenomic (Sargasso sea) projects were aggressively assembled by using a prefix tree. Data sets are stored in hash tables and the assembly process goes through a number of iterations searching for progressively shorter 3’-most *k*-mers for every new read added into the assembly. This approach allowed a complete assembly of the PhiX174 genome and generation of reasonably long contigs covering the nonrepetitive regions of viral, microbial, and even metagenomic samples.

These were the first attempts to satisfy the growing need for advanced NGS assembly tools. In recent years, numerous assemblers have been created to assemble genomes sequenced with different sequencing technologies and approaches (Table 2). Majority of the newly developed assemblers use the de Bruijn graph approach to assemble genomic data. They aim to assemble genomes of different size (microbes, fungi, mammals, plants) and complexity (haploid, diploid).

One of the most notable microbial assemblers nowadays is SPAdes (St. Petersburg Academic University, Russia) (Bankevich et al., 2012; Nurk et al., 2013). This tool, while originally developed for the purpose of overcoming the complications associated with single-cell microbial data (uneven coverage and increased level of chimerical reads), was recognized by the scientific community (Magoc et al., 2013) as one of the best assemblers working with both isolates and single-cell data. The latest version of SPAdes allows working with different combinations of sequencing platforms including Illumina, Ion Torrent, PacBio and Sanger using both paired-end and mate-pair libraries of different insert sizes. Its error correcting modules (BaseHammer (Nikolenko et al., 2013) and IonHammer) ameliorate read quality prior to assembly and then later on quality of assembly is once again improved by running repeat resolution and scaffolding modules.

For greater details on algorithms used in different assemblers please read (Miller et al., 2010) and follow the links in Table 2.

Assembly of Metagenome Sequences

The interest in conducting genomic analysis of microbial communities that exist in a variety of natural habitats gave birth to Metagenomics and led to the appearance of numerous metagenomic sequencing projects. The Whole-Genome Shotgun sequencing approach was successfully used for a number of uncultivated microbial community projects. Despite this fact, assembly of shotgun-sequenced metagenomic DNA poses a serious challenge to traditional assembly methods that were developed to handle relatively uniform sequences derived from isolated microbes. In addition to the typically very large size of metagenomic sequencing projects, potential problems observed in metagenomic assemblies include chimeric contigs produced by co-assembly of sequencing reads originating from different species, and nonuniform sequence coverage resulting in significant under- and overrepresentation of certain community members. Communities with one or two highly abundant members represented by several strains can add to the complexity of metagenome assembly due to the presence of extensive strain-level heterogeneity. As a result, often times a nonuniform assembly of the genomes of these abundant members is produced. Depending on the assembler used and sequencing read depth, some fragments are resolved into strain-specific contigs corresponding to different haplotypes, while others are co-assembled into composite contigs with strain-specific variations appearing as single-nucleotide polymorphisms. Large-scale genome rearrangements and the presence of mobile genetic elements (phage, transposons) in the abundant community members result in assembly break points in the areas of synteny breakdown. Many parameters of metagenomic assemblies remain unknown, including the nature and extent of chimeric contigs, influence of the level of polymorphism on co-assembly of reads into composite contigs, overall quality of assemblies and binning (process of separation of scaffolds into species-specific groups), and so on. Assembly accuracy is essential for metagenomic projects since it has much more influence on subsequent analysis and interpretation of metagenomic data than in cases of individual microbes due to coverage-related increases in consensus error rate. Currently, there

Table 2 NGS assemblers

is no single best pipeline to follow since each assembly program, each gene prediction algorithm, and each method of binning possesses its own set of benefits and problems. Moreover, each environment has its own particular complexities that are best dealt with using a combination of several tools for analysis. The high complexity and heterogeneity of metagenomic data call for an evaluation of the performance of different assembly tools on metagenomic sequences and require modifications to the assemblers and additional quality control throughout the entire process. To improve the quality of metagenomic assemblies, reads should be stringently quality- and vector- and adapter-trimmed prior to assembly (tools like Lucy, MAGIC-SPP, AdapterRemoval and Cutadapt, can be used for this purpose) and all possible attempts should be made to control quality of metagenomic assemblies produced. Assemblers containing modules to correct sequencing errors and to automatically detect and correct assembly problems (Arachne (Batzoglou et al., 2002), Phusion (Mullikin and Ning, 2003), EULER-AIR (Zhi et al., 2007; Table 2) can be used in metagenomic project assembly.

Depending on the complexity of the microbial community and the representativity of its members, assembly can contain a significant number of unassembled reads (up to 100%). As a result, some researchers choose to forgo assembly and instead focus analyses directly on the unassembled reads. While this method makes sense, genome assembly helps to diminish the size of the dataset for faster processing of further analysis. In addition to that, analytical tasks such as gene finding and taxonomic classification become much easier when applied to assembled contigs.

Several strategies can be used for Metagenomic samples analysis. Reference-based assembly can be done with software packages such as AMOS, or MIRA. These software packages include algorithms that are fast and memory-efficient. Reference based assembly works well, if the metagenomic dataset contains sequences where closely related reference genomes are available (Wu et al., 2009). Several tools are currently available for metagenome de novo short read assembly (MetaVelvet (Namiki et al., 2012), Meta-IDBA (Peng et al., 2012), Meta Ray (Boisvert et al., 2012)).

Directed sequencing is another approach used for metagenomic projects. This is based on the selective sequence of large-insert library clones of interest. The set of clones is screened for a desired function or the presence of phylogenetic markers. Shotgun and directed sequence approaches can be combined to help each other: random sequencing of large-insert libraries guides the selection of clones for complete sequencing using either traditional Sanger sequencing or one of the second generation DNA sequencing methods. This combination brings together the advantages of broader coverage provided by shotgun sequencing with the ability to sample specific genome areas in low-abundance organisms without oversequencing more abundant members of the microbiome. Despite the difference in sequencing strategies, processing of data generated by these approaches faces similar challenges due to inherent incompleteness and lower quality of the sequence data, and in many cases due to unknown origin of each sequence fragment.

A metagenome specific avenue of data analysis, called binning, assigns sequence fragments of a metagenome to particular species population or broader taxonomic groups based on information such as sequence similarity, sequence composition or read coverage. This is used for draft genome reconstruction, when sequencing coverage is insufficient for reconstruction based on assembly information alone.

Sequencing of paired-end and mate-pair libraries greatly improves genomic assembly by providing information about distances between two individual reads that can help with repeat resolution and contig scaffolding. The ordering and orientation of contigs within a scaffold can be used to check binning quality, which is why binning has been used to refine assembly in a feedback process. In recent studies, the combination of metagenome sequencing and taxonomic binning allowed to reconstruct several partial genomes.

Advances in metagenomic assembly will facilitate the linkage of function and phylogeny through the analysis of the assembly itself, but the assembly also helps with examining genetic variation and environmental distribution through fragment recruitment of different metagenomes to the assemblies.

Single-cell genome assembly

Single-cell genome assembly is a fairly new and challenging task. The main difference between single-cell and regular data sets becomes apparent when a whole genome amplification (WGA) method is used in order to amplify enough gDNA for the subsequent genomic library creation step.

As can be deduced from the term 'single-cell' this approach begins with a unique cell and therefore a very limited amount of gDNA starting material is available for the genomic project. Single cells can be isolated from the environment samples using such lab approaches as flow cytometry, micromanipulation, microfluidics, serial dilutions, laser capture microdissection, and fluorescence-activated cell sorting (FACS). The most popular WGA widely used for microbial single-cell gDNA preparation is called multiple displacement amplification (MDA) (Lasken, 2009). This method, while providing a sufficient amount of gDNA, complicates genome assembly by generating highly uneven coverage of the genome, as well as causing production of a significant amount of chimeric reads and reads with higher error rate. To overcome these problems new assembly algorithms and new single-cell assemblers (EULER+Velvet-SC (Table 2), SPAdes (Table 2), IDBA-UD (Table 2)) were developed. Another factor that affects assembly quality is the inconsistent outcome of MDA experiments ranging from a very low level of genome recovery to nearly complete reconstruction of the genome.

Nevertheless, single-cell genome sequencing is a powerful approach that demonstrates great promise for environmental biology since for the moment the majority of microbes cannot be grown in a lab environment and this is the only way to study them.

The recent development of a new amplification method called MALBAC (multiple annealing and looping-based amplification cycles) that 'introduces quasilinear pre-amplification to reduce the bias associated with nonlinear amplification' (Zong et al., 2012) was successfully applied during single human cell analysis. This opened the door for genomic studies of heterogeneous clinical samples, rare cell types, single-cell transcriptomic analysis and will undoubtedly have a significant impact on biology and medicine overall.

Genome Assembly Improvement and Finishing

None of the sophisticated computer algorithms described above is able to automatically reconstruct the entire genome from sequencing reads. They all produce so-called 'draft' assemblies, which are never perfect. Typically, there are problems such as misassembled areas usually caused by repetitive regions (repeats), sequence and physical gaps, areas of low coverage and/or poor quality. The better the assembler can handle such problems, the higher-quality draft will be created and the faster and easier the assembly improvement step (finishing) will be. Finishing is the process of transforming a draft assembly into a finished one. During this step all repeats are identified and assembled correctly, all misassemblies are resolved, all gaps are closed, and all bases are identified with high accuracy. Thus finishing is the process of incrementally improving an assembly by using computational tools, techniques and experimental protocols. Despite the fact that a solid suite of software tools and web applications have already been created, finishing genomes remains a labor-intensive process. It requires experienced personnel and laboratory experiments to support finishing strategies.

It is commonly believed that finishing begins by the ordering and orientation of contigs (scaffolding) for subsequent gap closing. However, the experience collected during the course of assembly and finishing of more than 500 microbes demonstrates that it is more efficient to begin the process of draft assembly improvement with misassembly resolution. It is rather logical, since incorrectly assembled contigs lead to the construction of erroneous scaffolds, created on the basis of false connections. In addition to real gaps, such assemblies will contain pseudo gaps. All this in turn will lead to further complications and the lengthening of the finishing process.

The areas of potential misassemblies can be recognized at different stages of genome assembly via the application of different methodologies. Some assemblers can identify and even correct repetitive areas during the assembly process (Figure 3). Some of them use paired reads information (detecting areas of clone mate inconsistency including reads placed too far apart, too close together or incorrectly oriented pairs), statistical information (areas of significantly higher coverage than the average) or mask out repeats (in this case additional efforts for assembly of repeats are required). Up to 80% of the repetitive areas can be addressed automatically, while the remaining ones (the most ambiguous) need additional laboratory experiments and manual efforts for their resolution. Additional tools have been developed for more effective detection of repeats. They can be used after the initial draft assembly has been created. For instance, RepeatMasker locates repetitive areas and excludes them (masks) from further searches for similarity regions. In addition to the exact repeats, a tool named REPuter recognizes degenerate repeats thus allowing for a certain rate of sequence errors. It is able to detect not just direct repeats, but also palindromic repeats and other closely related sequence features. Tools like equicktandem, mrep, and Tandem Repeat Finder find tandem repeats of certain size by using statistical (equicktandem) or heuristic (mrep, Tandem Repeat Finder) algorithms for their detection. Another software package, Vmatch, represents a collection of programs, for solving large-scale sequence matching tasks.

Repetitive elements can be of different size and may differ from each other by one or more bases. Most repeats of 2–3 kb are due to insertion elements. Multiple copies of ribosomal DNA sequences represent longer repeats of 5–8 kb. In some microbial genomes, repetitive elements of 70–100 kb were observed. They represent duplications of large areas of the genome, which could have occurred during the course of evolution of the particular microbe in question. Besides being differentiated by their length, repeats can be split into three categories by type: direct, inverted, or tandem repeats (Figure 4). While direct repeats and different copies of tandem repeats can collapse in one location or become rearranged during the assembly, copies of inverted repeats may be assembled in the wrong orientation thus creating pseudo physical gaps (Figure 4). By using for example the Miropeats program one can draw a graph that will help to distinguish tandem repeats, inverted repeats and palindromes; however, biological

Fig. 3 Draft assembly views of *Burkholderia phytofirmans* PsJN (GenBank <http://genbank:AAUH000000000>): (a) Assembly produced by phrap; (b) Assembly produced by PGA. Grey boxes represent contigs. Purple lines above the contigs represent clones that span gaps between contigs and join them. Lines of different colors below or between contigs indicate misassembled paired reads.

Fig. 4 Types of repeats and potential misassemblies. Repeats: A – direct repeat; B – inverted repeat; C – tandem repeat. Misassemblies: A – incorrectly linked non repetitive areas *a* and *b*, located up- and downstream of the direct repeat; B – pseudo physical gap caused by incorrect placement of copies of inverted repeat; C – collapsed copies of tandem repeat; D – rearrangement of identical or nearly identical copies of repeats (1 – correct order; 2 – misassembled area).

duplication events and assembly mistakes cannot be distinguished by this program. Another open source graph visualization software Graphviz represents structural information as diagrams of abstract graphs and networks and is widely used for genome assembly visualization and analysis.

One of the commonly used approaches to repeat resolution consists of the following steps: repeat localization, identification of the reads belonging to each repetitive element, pooling of (grouping) the defined reads, their assembly into separate subassemblies for each individual copy of a repeat and exporting the resulting consensus back to the main assembly as one ‘long read’ (fake read) for each subassembly. Tandem repeats represent the greatest problem in successful repeat resolution. They are especially troublesome if the length of one copy is longer than the insert sizes of the libraries available for the sequencing project. The reads belonging to different copies of a repeat and entirely lying within the repetitive region collapse into one pile during draft assembly. This means that assembler produces fewer copies of the repeat than the finished sequence contains. Because the library clones/fragments are not uniformly distributed over the genome, it is not sufficient just to estimate the extent of increased coverage in the area to discover the number of copies of a repeat gathered in such piles. An *in vitro* transposon insertion strategy involving a random insertion of a yeast transposable element into a repeat-covering, circular plasmid is one of the most powerful experimental approaches for tandem repeat resolution. Transposon ‘bombing’ allows random identification of new sequencing start points within the repeat and the generation of new sequence directed away from the insertion points.

Some modern assembly tools have repeat resolution and miss-assembly solving modules build in. For example the exSPAnde algorithm (Prjibelski et al., 2014) used in SPAdes assembler for repeat resolution, accurately resolves repeats when both single and multiple NGS libraries of read-pairs provided for standard and single cell assembly projects. In hybrid Illumina/PacBio or IonTorrent/PacBio assemblies SPAdes uses PacBio CLR reads for gap closure and repeat resolution. It can also use high quality contigs of the same genome generated by other assembler(s) and merge them into SPAdes assembly. Such contigs will be used for graph construction, gap closure and repeat resolution. If assembler is provided with preassembled contigs of a poor quality, it will use them for gap closure and repeat resolution only and will build a graph using Illumina or IonTorrent reads. ExSPAnde as well as Ray and Telescope (Bresler et al., 2012) assemblers use a simple path extension approach for repeat resolution and combine it with some ideas from the Rectangle Graph approach.

After all the misassemblies have been resolved, it is time to fill in the gaps between the contigs, in order to produce contiguous sequence for each DNA. In practice, the process of closing gaps between the correctly assembled contigs can be started in parallel with repeat resolution.

aired reads information and the knowledge of the library insert size distribution allow ordering and orientation of correctly assembled contigs and organizing them into scaffolds (Figure 2). Software tools called scaffolders were created to assist finishers in this complex task. Consed and Bambus are among the most popular tools of this type. These and other similar programs (e.g., scaffolders within several assemblers – Table 2) provide a global overview of the interdependency between the contigs, and help with selection of particular clones that contribute to bridging gaps and planning of finishing experiments.

Small sequence (captured) gaps can be closed by custom primer walking on the existing clones (in case of Sanger libraries) that span gaps. Such clones can be distinguished by the presence of the sequence from each end of the insert in two separate contigs. During the primer walking procedure a custom primer designed for the end of the contig is used to perform sequencing reactions to

extend sequence information into the gap. This process is repeated until the entire gap-spanning plasmid is sequenced. It is faster and more cost efficient to close captured gaps of 5 kb or longer by transposon 'bombing' of gap-spanning clones (Epicenter Biotechnologies) or by producing a shatter library of appropriate plasmids or PCR fragment. In the shatter method, the chosen DNA template is sonicated into fragments of 100–300 bp, which are then subcloned into a vector and sequenced by using standard vector primers.

Many captured gaps are difficult to sequence by primer walking. Problems usually arise due to the presence of strong secondary structures (very common in genomes with GC content higher than 65%) and hairpin structures and/or long homopolymer stretches in the DNA. Sequencing very short inserts produced by shatter libraries usually helps with most DNA structures because only a small part of the secondary structure or hairpin is cloned. Short read NGS technologies also break down secondary structures or hairpins.

Linking information, usually provided by sister reads, is not available for physical gaps, existing between contigs or scaffolds. Sometimes the comparative analysis of closely related reference and target genomes can provide a clue for contig mapping. If the end sequences from the two contigs encode two different parts of the same protein, it may be assumed that these contigs should be linked. It has also been shown that the gene composition of some operons is very well conserved between genomes. This information can also be used to link the contigs containing parts of such operons at their ends. Several software tools have been developed to assist with this analysis by comparing the entire genomes or contigs from different assemblies against each other and against reference genome(s) (GMPTB, MUMmer, Projector2, SIBELIA and so on). Such assisted assembly strategies go beyond just helping with gap closing. They offer an opportunity to sequence new organisms to less than the typical sequence depth. For those cases in which none of the approaches described above is helpful, direct laboratory experiments need to be performed. For example, a technique called optical mapping compares the assembled contigs against the collection of restriction maps of a DNA molecule. Each map produced by a rare cutting restriction enzyme serves to order and orient contigs and scaffolds separated by uncaptured gaps. Selected restriction fragments can be used as templates to produce the sequence for gaps.

The recently developed BioNano Irys approach for generating optical maps attaches fluorescent labels to the specific sites of the DNA using single-stranded DNA nicks. Then the DNA fragments are linearized in nanochannels and images are taken with a CCD camera. The images are processed to obtain positions of the labels along each genomic fragment. The fragments are typically 100–200 kbp long and the labels are located approximately 5–10 kbp apart depending on the nick pattern selected for inserting the fluorescent labels. Combined with genome assembly this technique significantly improves repeat resolution and scaffolding steps.

When no other templates are available, polymerase chain reaction (PCR) products generated across the gaps can be used to map contigs or scaffolds and to produce sequence for the gaps. In order to build a PCR map, unique primers are designed for the end of each contig (it is necessary to make sure that primers correspond to regions outside of repeats) and used in a PCR experiment to test whether a particular pair of primers links the contigs. This approach is not feasible in the case of large numbers of contigs to be mapped, since it requires too many PCRs to be performed and analyzed.

An improved version of the combinatorial PCR method, Multiplex PCR, was developed to optimize this process. This approach is based on the simultaneous use of multiple primers (up to 32) in mapping experiments with further analysis of which two primers made the PCR fragment (Figure 5 schematically represents the use of Multiplex PCR approach for mapping of four contigs).

The advantage of the Multiplex PCR method versus the combinatorial PCR approach, where each end primer is verified against all others except the one that was designed for the second end of the same contig/scaffold, is that it requires fewer PCRs to map the contigs. Thus, to order and orient four contigs (Figure 5) one should perform nine multiplex reactions instead of 24 combinatorial ones. The difference becomes more prominent when larger numbers of contigs are involved in the experiment (only 17 multiplex PCRs versus 120 combinatorial PCR reactions are needed to map eighth contigs). The PCR products thus obtained are sequenced to close the gaps between mapped contigs or scaffolds.

Sequencing and mapping complications associated with strong secondary structures and unclonable areas present significantly fewer challenges for the second generation of sequencing technologies, as the majority of them rely on assembly of very short overlapping fragments and do not require fragment cloning in *E. coli*. As a result, 454 contigs, assembled by the Newbler assembler effectively cover physical gaps, produced by WGS. The highest success rate was observed for genomes with low GC% (<40%), for which a combination of Sanger and 454 sequencing was used. Such a combination allowed closing of up to 100% of uncaptured gaps (Figure 6) (unpublished data). The 454–Sanger combined approach also allowed the completion of the uncultured Gram-positive bacterium, *Candidatus Desulforudis audaxviator*, from a low-biodiversity water fraction collected at 2.8-km depth in South Africa.

In addition to the above-mentioned problems, a typical whole-genome draft assembly contains low-quality regions and regions poorly covered by clones or fragments. For the genome to be considered finished such areas should be improved by resequencing of the existing clones or of the appropriate PCR products (so called polishing step). Illumina and other new technologies, are very valuable for faster and cheaper polishing of microbial genomes. Results originally reported at the Advances in Genome Biology and Technology meeting (AGBT) in 2008 supported this notion: a Solexa/Illumina run aligned to a 454-assembled bacterial genome identified (and allowed correction of) 98% of frameshifting indels. More importantly, the remaining frameshifts were in fact true indels in the genome.

To completely wrap up a microbial project it is necessary to confirm the correctness of the final assembly and the accuracy of the finished sequence. The sequence quality standard used for Human Genome sequence data and named 'Bermuda' standard (1 error per 10 000 bp) has also been accepted in microbial sequencing. The final human inspection step supported by visualization tools (DNPtrapper, Hawkey, Orchid) aims to verify that all bases of the produced consensus are supported with enough coverage

Fig. 6 Assembly views of *desulforudis audaxviator*: (a) draft assembly; (b) assembly after repeat resolution and two rounds of primer walk; (c) assembly after repeat resolution and two rounds of primer walk combined with 454 data (for details see legend for Figure 3).

(less frequently observed with new technologies), that consensus quality corresponds to the agreed standards (1 error per 100 000 bp for NGS assemblies), that all produced reads are correctly assembled (consistent), and that all repetitive areas are resolved (Chain et al., 2009).

Progress in DNA sequencing technology, improvements in finishing strategies and tools, as well as the availability of a number of assemblers and advanced methods for genome annotation have significantly reduced the time required for genome closure.

Despite this fact, the effort and time required for genome closure depends on the quality of the whole genome shotgun libraries created for the project, GC content of the genome, the size and frequency of identical or nearly identical repetitive structures, and the number of regions that cannot be cloned or are hard to clone in *E. coli* (if the cloning step is involved in a project). A finished genome represents the genome assembly of high accuracy and quality (with no gaps), verified and confirmed through a number of computer and lab experiments. The value of complete microbial genome sequences has been long established and appreciated by the scientific community. In addition to the genes that differ by a very few bases from each other and thus co-assemble in draft assembly, the genes coding for proteins toxic for *E. coli* remain undetected by the analysis of incomplete genomes. Furthermore, new sequencing technologies, developed for genome resequencing (Solexa/Illumina, SOLiD, IonTorrent) as well as the growing interest in metagenome sequencing projects, dictate a greater need for high-quality references. A significant number of microbial genomes still needs to be sequenced to full completion for successful use of new sequencing platforms in many areas of general microbiology, ecology, evolutionary studies, and so on.

The DOE Joint Genome Institute has established a project named GEBA (Genomic Encyclopedia for the Bacteria and Archaea), which is focused on filling gaps in the Tree of Life and has the long-term goal 'to generate reference genomes for every major and minor group of bacteria and archaea'. This is spearheading a major expansion of knowledge of bacterial phylogeny.

Third-Generation Sequencing and Genome Finishing

The best way to correctly assemble repeats, consequently not only closing, but possibly even avoiding gaps in assembly all together, is to generate reads that are significantly longer than the repeats themselves. This way they can unambiguously traverse repetitive areas. Pacific Biosciences (PacBio) is the first sequencing technology that allowed production of reads up to 15 Kbp long. Random error profile helps eliminate the problem associated with the high error rate (14–15%) of reads. Sufficient sequence coverage and/or error correction (Koren et al., 2012) significantly improve the quality of the consensus.

Looking at the PacBio production level one can ask why use PacBio when we get so much more data out of the Illumina sequencers? The answer is simple – single molecule approach enables unique opportunities for overcoming such short-falls of Illumina platform as GC bias, hard stops, need for multiple (short insert, mate pair, chemical methylation detection) library preps. Long reads, fast turnaround, flexibility to get high quality single molecule consensus (short insert CCS) or long reads for assembly/scaffolding/gap closure make this technology very advantageous.

This long read sequencing technology started the so-called third generation sequencing technology revolution that is currently being supported by Illumina (TruSeq synthetic long-reads), Oxford Nanopores, BioNano (Irys technology) and other companies. Such read length and consensus accuracy (up to 99.9%), as well as new assembly tools (Dazzler (the Dresden AZZemBLER); SPAdes; AllPaths-LG; MIRA) and processes (HGAP (hierarchical genome-assembly process) (Chin et al., 2013)) will revive the production of completely assembled reference quality (Chain et al., 2009) microbial genomes that was slowed down for the last several years due to both high cost and labor intensiveness of finishing. An automated pipeline called PBJelly aligns long sequence reads to draft assemblies in order to close or improve captured gaps. It is currently applicable to PacBio RS reads, but can be generalized to any long read data.

The crucial role of completely finished microbial genomes in comparative genomics, metagenomics, diversity studies etc was already discussed above.

Assessing Quality of Draft Genome Assembly

Large amount of assemblers currently available for researches (not all of them are listed in this review) address many different aspects of genome assembly complications, but none of them are able to solve them all. This means that none of them are perfect and one has to decide which particular instrument to select based on the specifics of the project being worked on. Furthermore, assemblers can create different assemblies depending on the data sets provided and assembly parameters chosen.

Assembly evaluation tools can help answer the question of what assembly is better for further analysis by assessing the quality of an assembly and comparing different assemblies against each other. Developers of such tools need to choose what metrics to use to assess the assembly quality. Tools should work without relying on the high quality reference genome and be convenient for users with any level of experience (the latest requirement is true for most of other tools including genome assemblers).

QUAST (Gurevich et al., 2013) and GAGE (Salzberg et al., 2012) are the two most popular tools of this type used for microbial genome assembly QC. These tools compute different metrics to assess the assembly quality. The most common metrics used are: the total number of contigs in the assembly, the length of the largest contig, the total length of the assembled contigs and N50 (N50 length is the length of the shortest contig in the whole set such that the sum of contigs of equal length or longer contains at least 50% of the total length of all contigs). Parameter N50 becomes absolutely useless if the contigs are incorrectly assembled. So, additional information on misassemblies is very valuable. All of these and any other additional metrics should never be considered in isolation, since they begin to make sense only when being considered in combination with other assembly characteristics.

NCBI Trace and Assembly Archive

The Trace Archive was established in 2001 to collect raw data produced at sequencing centers around the world. This depository represents a collaborative effort between NCBI (<http://www.ncbi.nlm.nih.gov/>), European Molecular Biology Laboratory (EMBL/ENSEMBL) and DNA DataBank of Japan (DDBJ) and it currently (04/13/2014) contains 2 178 623 682 traces. The amount of data in the archive doubles approximately every 18 months and new sequencing technologies as well as large sequencing programs like the Microbial Earth project, Earth Microbiome Project, 100 K Pathogens, The Human Microbiome Project, Genome 10 K, 1000 genomes etc. will result in an even higher rate of data increase in the future. To accommodate massive flow of short sequencing reads generated by the next generation sequencing technologies NCBI has constructed (2008) a new repository named Short Read Archive (SRA).

NCBI's SRA, Trace and Assembly Archives (The Assembly Archive created at NCBI in 2004 (Salzberg et al., 2004) provide direct access to the raw traces and assemblies and give researchers a unique opportunity not only to reconstruct the assembly from raw shotgun and finishing reads obtained from the Trace Archive and/or SRA, but also to verify the quality of the assembled genome and its accuracy. Any potential or real frame shifts detected in the course of genome annotation can be thus double-checked and corrected on the basis of the details of assembly.

Because different sequencing centers and individual researchers use different tools to assemble sequences, the generated assemblies may come in a variety of formats. Regardless of the specific format, the data can still be submitted to The Assembly Archive, following detailed information provided in the NCBI Assembly Submission Guide.

Fig. 7 Assembly viewer display of *Salinispora tropica* CNB440 draft assembly (<http://www.ncbi.nlm.nih.gov/>). The overlapping traces comprising the assembly and detailed alignments are shown.

Fig. 8 The underlying sequences and traces from the draft assembly of *Salinispora tropica* CNB440.

Fig. 9 Snapshot of the single-nucleotide polymorphism (SNP) VISTA viewer for the metagenomic project of acid mine drainage.

Figure 7 illustrates one small region of multiple sequence alignment of reads to the *Salinispora tropica* CNB440 genome sequenced at JGI. Another function made available by The Assembly Archive is the ability to see the individual bases in the DNA sequence by examining the aligned traces (Figure 8).

This is the feature that opened the door for analysis of single-nucleotide polymorphisms (SNPs) in a broad range of eukaryotes and for the haplotype analysis of metagenomic assemblies. The haplotype analysis of metagenomic data can also be performed in IMG/M (<http://img.jgi.doe.gov/>), a metagenome data management and analysis system developed by the DOE Joint Genome Institute (Figure 9).

Glossary

α-Diversity Is the mean species diversity of a given sample or site, as opposed to β-diversity which takes into account the species diversity across different sites.

Average nucleotide identity (ANI) scores In the pregenomics era, a bacterial species was defined if 70% of the DNA from two bacteria hybridized in the molecular biology technique known as DNA–DNA hybridization (DDH). In 2007, the Kostas lab introduced the ANI scores by comparing DDH values to those of whole genome comparisons of those strains whose genomes were available at the time. Using both best hits (one-way ANI) and reciprocal best hits (two-way ANI) between two genomic datasets, they established a threshold of “same species” where their ANI values are above 95% (e.g., *Escherichia coli*). ANI values below 75% are not to be trusted. They keep an online tool, the ANI calculator that supports the comparison of any two genomes to be uploaded.

Barcode gene The term barcode, referring to the one you find on groceries, induces the idea that, ideally, any species could one day be identified simply by scanning a piece of genomic DNA and looking into the appropriate reference table to find the perfect match. Until that day comes, we'll have to settle for SSU genes (16S rRNA for prokaryotes and 18S rRNA for eukaryotes).

Clustering Clustering algorithms have the goal of grouping a set of objects, in this case, sequences, that are more similar based on certain criteria (usually, sequence identity). In the metabarcoding context, the process of iteratively assembling reads picked from a pool into OTU groups (or a taxon). It generally consists on aligning and measuring similarity/distance between read sequences.

Data Warehouse Is a collection of data from varied sources to provide meaningful insights blending components in order to allow the strategic use of data.

HMM A Markov model is a statistical model in which the probability of an event depends on the immediately previous event. In a HMM (for hidden Markov model) the parameters of the process are “hidden” and the challenge is to determine them from the observable data.

OTU Stands for Operational Taxonomic Unit.

Quality score Describes the quality associated to each base pair in a raw-read.

Raw-read Are those generated directly from the sequencing company, without any postprocess such as cleaning, trimming, adapter removal, etc.

Speciation Through accumulated mutations, specific niche adaptations, and isolation, organisms evolve to form new divergent species.

Taxon A monophyletic group of sequences or organisms that form a unit, which could be a species.

Introduction

When the previous edition of this encyclopedia was printed 10 years ago, bioinformatics had a different meaning and was applied differently. Although some techniques/approaches have not changed, we have clearly moved from studying single strains to studying microbial communities. Although we have learned a lot by studying model organisms, there is also a benefit in understanding how they interact with other members of their natural habitat, with the environment, and with their hosts. Focus may then be moved towards the particular physiology of that organism to understand its role in the ecosystem, and then back to the ecosystem to understand the metabolic functions of the global community. On top of studying individual species, we now aim to understand microbes and their communities. How do microbes behave in their respective ecosystem? Which metabolic functions do they perform? Do they do it by themselves or do they share the pathways with other commensals and interchange metabolites? Who are the primary producers in the community? Who fix carbon and who are the ones that ferment the byproducts made

[☆]*Change History:* January 2019. A. Gutiérrez-Preciado et al. have made major changes to the references and text.

This article is an update of A.G-Preciado, M. Peimbert, E. Merino, Genome Sequence Databases: Types of Data and Bioinformatic Tools, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 211–236.

available to the rest of the inhabitants? Once we know the identity of the major players and their genomes are available, more specific questions can be addressed. Which gene codes for a given transcript or protein that performs a particular function in a specific organism? How, and to what extent, is such a gene regulated? What is the three-dimensional structure of its corresponding protein? What other transcripts or proteins participate in the cellular pathway? Which scientific articles are related to this gene, protein, or pathway? If we change to a different ecosystem where the same genes and the same pathways are found, is the same organism the one that is performing such an action? Are there representative (core) organisms of certain environments? Or is it more that there are core metabolic functions for each ecosystem? Can the pattern of the present/absent species serve as a bioindicator of a healthy ecosystem?

This article will focus on the great advances that have changed bioinformatics in recent years, with a special spotlight on microbial communities, and an aim to review the tools and databases that may aid in answering these questions through either sequencing or accessing the enormous sequence collection the scientific community has gathered. In bioinformatics, there are no golden rules on how things should be done. The same problem can always be solved in several ways and, as such, for each problem, there are often multiple bioinformatics tools available to deal with it in different scenarios. We describe here a set of tools that we have found useful in our own experience but encourage the reader to go further and explore additional bioinformatics tools to gain a wider perspective on their microbial communities of interest.

Data Sources

The last 10 years have witnessed the democratization of high-throughput sequencing, to such extent that, in a single day, state-of-the-art sequencers can produce the equivalent of the entire nucleotide archive available when the previous edition of this encyclopedia was published (see Fig. 1). This massive amount of data has led to new challenges in bioinformatics, starting with storage issues, as nowadays it is cheaper to “read” a nucleotide than to permanently store its identity, position, and sequencing depth, all the way up to the dedicated analyses providing biological insights. In this section, we will cover how and where sequences are stored; and what kind of analyses can be performed in order to best utilize our sequence data.

Sequence Repositories

Sequencing machines do not really “read” biological polymers; instead they transform their read-out (i.e., the fluorescence associated to the release of a labeled pyrophosphate or the characteristic interference of the electrical current while a single biopolymer passes through a pore) into a string of characters. While the real “raw-reads” are the machine’s read-outs, these are most commonly only available to whoever has paid for the sequencing, and seldom analyzed for other uses than quality control (although some can include biologically relevant information, such as base modifications that produce distinct read-outs, like methylation). For researchers outside of sequencing centers, the term *raw-read* is more often used to refer to the string of characters and an associated *quality score* that specify how confident the identity of a character is based on the sequencing reaction, itself depending on the sequencing chemistry and the local sequence properties. The character strings and their associated quality scores are stored in a human readable format called *fastq*. The sequence is stored in conventional *fasta* format and the quality scores in a legacy format called *phred*. Each read thus is stored in four consecutive lines, two normally containing the “read” identifier (header starting with “@” for the sequence and with “+” for the quality scores), one containing the sequence string in standard one letter code, and one containing the associated quality scores. Compressed *fastq* files are publicly stored in sequence repositories, the largest one being the Sequence Read Archive (SRA) from the International Nucleotide Sequence Database Collaboration (INSDC), consolidating data held by the National Center for Biomedical Information (NCBI), the European Bioinformatics Institute (EBI), and the DNA Data Bank of Japan (DDBJ).

About 21,078 of the entries in the SRA correspond to experiments of whole genome amplification, another 627,669 to RNAseq experiments (nearly half without reference genomes), 690,550 to metabarcoding and 111,155 to WGS metagenomes, these latter being particularly enriched with microbes lacking cultured representatives. Repositories of assembled genomes are presented in a dedicated chapter of this encyclopedia. How much of the total length is covered (completeness), how many times each position was identified (depth or coverage), what proportion of conserved genetic elements does it contain (representation) and the difference between assembled elements and chromosome-like structures (contiguity) are all important metrics to assess the quality of a genome assembly. While most whole genome assemblies can be accessed through the sites of INSDC members, dedicated gateways, such as *EnsemblGenomes* and *GOLD* offer single entry points to finished and draft genomes. The *GOLD* repository also includes records from environmental samples, also known as metagenomes. The website *Integrated Microbial Genomes (IMG)* integrates viral, bacterial, archaeal, and selected eukaryotic genomic data collected from multiple data sources. It has an extended metagenomic *warehouse: IMG/M*, which is a data management and analysis system that provides tools and viewers for analyzing both metagenomes and isolated genomes individually or in a comparative context.

Besides being the underlying data for de novo genome or transcriptome assembling, sequence reads and their quality scores are also used for reference-based quantification of DNA modifications (Chip-Seq), differential expression of RNA molecules (RNAseq), population genomics (SNPs), and genome architecture and organization (Hi-C). Despite few model species, most of these techniques and analysis are seldom, if at all, used in the context of microbial genomics. Still, sequence reads are also the main source of data for modern metagenomics. Indeed, after years of surveying for species presence (more often listing of operative

Fig. 1 Growth of sequencing archive as collected by the IMG database. (A) Trends in Sequencing Technologies in the IMG database. (B) Trends in Sequencing Projects in the IMG database.

taxonomic units (OTUs) based on hyper-conserved markers, i.e., the so-called meta-barcoding), the metagenomics field is now taking decisive steps into considering a more comprehensive representation of the biological diversity in all sorts of microbial communities.

Genome Analysis and Annotation Resources

Genome annotation is the process of overlaying other biological data onto the DNA sequence. While draft genomes might contain no annotation or include only basic information such as whether any particular base pair likely encodes a protein or not, genomes and metagenomes are most useful when they are close to completeness and rich in annotations. In the case of metagenomes, knowing the phylogenetic/taxonomic composition is also of paramount importance. To avoid duplication with other chapters of this Encyclopedia, we will limit this section to the introduction of some public resources that leverage already annotated genomes and metagenomes and we will close our article with an application note detailing *anvi'o*; a holistic bioinformatics platform to integrate and visualize all the data as different layers.

For many genome projects, the genome size is not known a priori and even when known, the coding density and redundancy is uncertain. So, how one can know if a draft assembly is already representative of the whole genome? Homologous genes conserved

across multiple taxonomic ranges tend not to appear in multiple copies (Single Copy Genes; SCGs) and the most closely related the taxonomic groups are, the larger will the group of conserved genes be. Identifying what proportion of such conserved, and conservative, genes are already covered by a given assembly, offers one of the quickest ways of answering this question. Implementations of the concept started back in the origins of phylogenomics in the form of Clusters of Orthologous Groups (the foundational, albeit outdated, COGs), later refined with more robust assignment of orthology (e.g., *phylomeDB*), and more recently benefited from the ever-increasing number of sequenced genomes (*BUSCO*).

Once annotations are available, genomes can be described and compared to each other. The underlying idea is that while similar genomic features (e.g., conserved protein families) would be the basis of common functions in the compared species or meta-communities, distinct genomic features should define what makes organisms or meta-communities unique. These analyses constitute the core of *comparative genomics*. The single-entry gateways presented above offer dedicated resources for microbial organisms (the *Integrated Microbial Genomes and Microbiomes*, IMG/M, and *EnsemblBacteria*, also including Archaea, *EnsemblFungi* and *EnsemblProtists*), including precomputed sets of orthologous genes. Another widely used resource is *OrthoDB*, a database of precomputed orthologous genes, which can be customized to display orthologous groups across up to 20 species. Conserved elements, such as single-copy orthologous groups, can then be used to resolve the phylogenetic relationships of the species under consideration.

Structure of Microbial Communities: Metabarcoding

Metabarcoding allows to quickly and easily screen the α -diversity of whole microbial communities without the need to culture organisms (Fig. 2). Barcodes are derived through sequencing a barcode gene that can be retrieved from genomic DNA extracted from homogenized biomass. Metabarcoding can describe the structure of very complex communities and has reshaped our understanding of the diversity of extant microbial life, exposing how much actual diversity was previously missed when relying only on cultures and microscopy.

Briefly, by massively sequencing the barcode gene of choice (usually the small subunit complex (SSU) of the ribosome, 16S rRNA for prokaryotes and 18S rRNA for eukaryotes), metabarcoding allows grouping and classification of living organisms into OTUs. OTUs are built upon the comparison of homologous DNA sequences from different organisms using a predefined and assumed difference metric.

Defining thresholds for OTU clustering is highly problematic. With SSU coding genes, there are two historical threshold values that have been widely used: 97% of similarity for 16S SSU rRNA sequences of prokaryotes and 98% of similarity for 18S SSU rRNA sequences of eukaryotes. How can we decide how much difference between sequences is not biologically discriminant? Since this will not always be true, the most recent algorithms dedicated to OTU inference allow “flexible” similarity threshold, or replace the fixed similarity value by local evaluations of informative variations for every read throughout a sample, taking into account the quality of the reads, the frequency of putative erroneous reads, and by measuring how informative are each position along reads.

Once OTUs are determined, the next step is to establish their biological identity. For this purpose, many dedicated reference databases have been built over the last two decades. Specialized databases provide the most reliable set of full-length barcode sequences in terms of sequence quality and taxonomic classification. The steps of defining the OTUs and assigning them a biological identity are key to unveiling the structure of the microbial community, and it is important to understand the algorithms and the resources available. It is worth mentioning that the common practice of inferring the taxonomy of OTUs using simple local similarity search tools like *blastn* can be misleading. More suitable strategies are available that involve a global pairwise alignment against the reference SSU databases (e.g., *SINA* or *NASt/pyNASt*), or phylogenetic placement (e.g., *pplacer*).

Finally, diversity analyses can be performed to understand the differential abundance of the inhabitants in the community and built co-occurrence networks of the OTUs with software such as *SparCC* to unveil possible interactions (e.g., symbiotic, commensalism, parasitism, detect key species, etc.; Fig. 2).

Application Note on Microbial Communities: Merging the “Omics”

Metagenomes aim to encapsulate the genetic pool present in the environment. Metagenomic datasets commonly comprise millions, if not billions, of short DNA sequencing reads and allow access to the entire genomic content of a wide range of abundant microorganisms, albeit in a fragmented form. In fact, sequencing reads are usually shorter than a gene. Nevertheless, metagenomics has proven itself a powerful approach to profile the taxonomy and functioning of microbial communities without relying on cultivation or metabarcoding.

In whole-genome sequencing projects, one might expect that the origin of the sequenced DNA is material anything but ambiguous. However, unintentional contamination and the throughput now standard in modern sequencing machines—in which multiplexed samples might come from very different or very similar organisms—have made necessary to develop sequence or composition based computational protocols to identify the likely origin of the sequenced DNA molecules. These methods can be and have been, used to resolve the taxonomic composition of metagenomes.

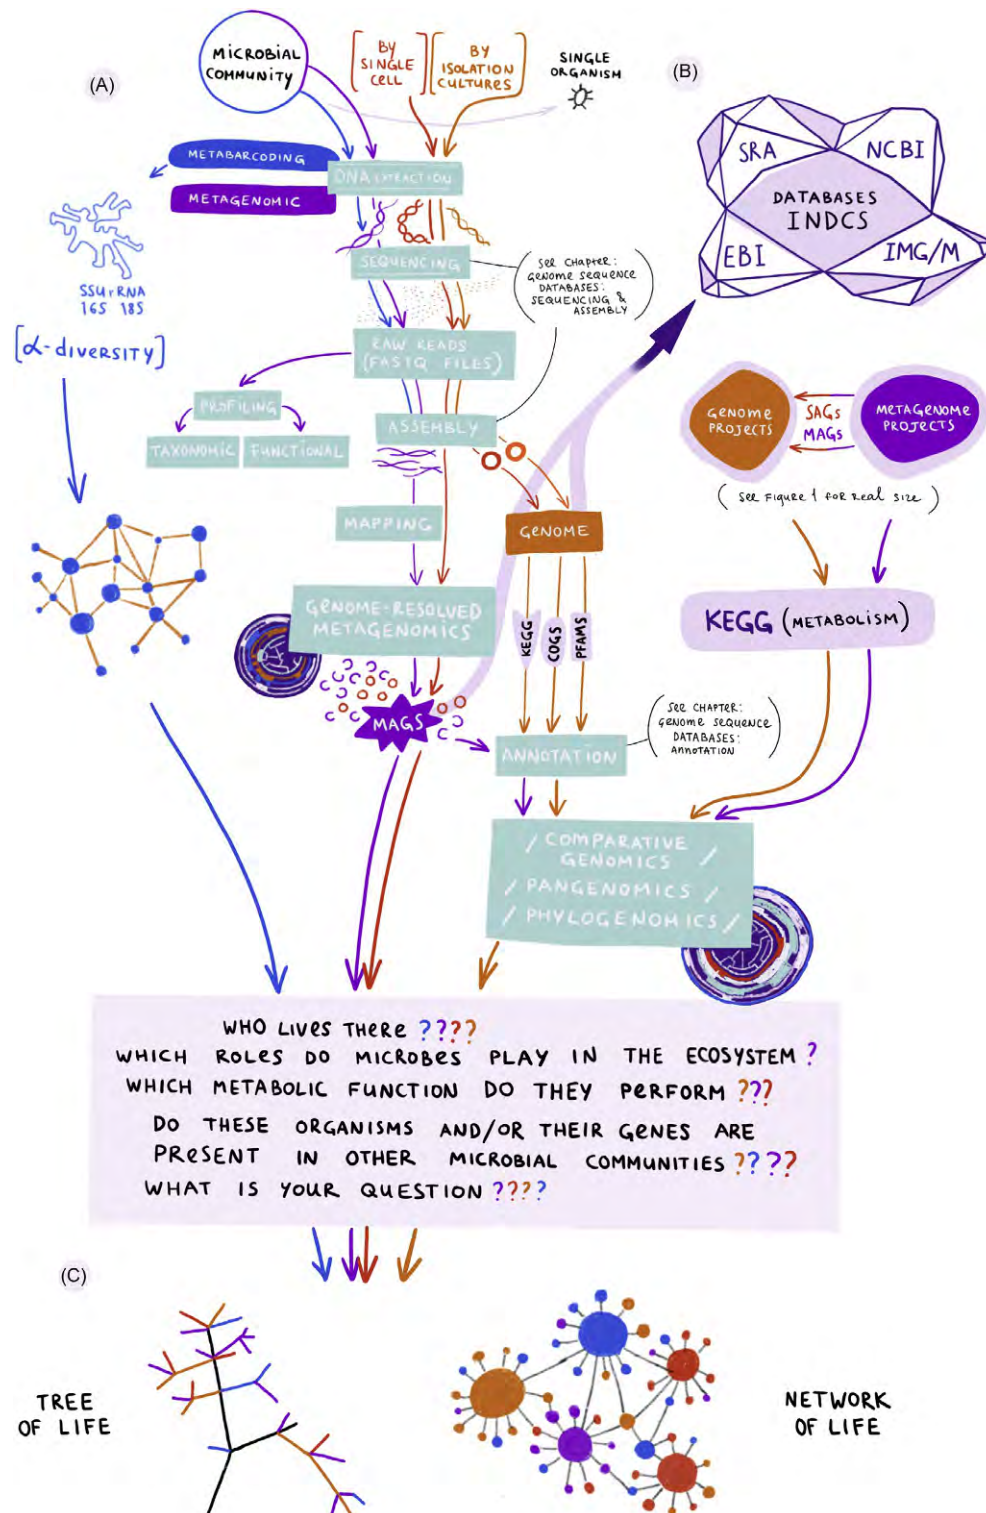

Fig. 2 A map through the Genome Sequence Databases, the Types of Data and Bioinformatic Tools. (A) The tools used to understand a microbial community through its genes, either by metabarcoding, metagenomics or genomics of an isolated microbe. The sequences generated from laboratories around the globe feed the (B) public databases, which are then used to contrast and compare new sequences generated from different microbial communities. All these tools and databases aid in answering biological questions which help the community to build an ever-evolving view of (C) the tree of life, and the network of life, through the evolution of the microorganisms and their interactions with each other. Artwork by Anna Ustrehova instagram: @ustrehova.

Profiling of a metagenome can be done twofolds: taxonomic profiling (who lives there) and functional profiling (what is the community capable of doing; Fig. 2). Profiling can be either performed at the read level, or at the contig level following an assembly process. Assembly of reads will not be covered in this chapter.

There is a large amount of software to assign taxonomy to reads. Some will focus on the *k*-mer composition of the reads (*Kraken*), others will perform a similarity search against a reference database (*MEGAN*) and others will exploit mapping algorithms (*Centrifuge*). Taxonomic assignment will depend on a combination of the selected algorithm and the database used, so it is important to keep in mind that taxonomic classification does not imply an evolutionary relationship.

Preliminary taxonomic and functional profiling of the reads is a useful guide for subsequent analyses and helps inform later decisions when adjusting parameters. It allows us to resolve taxa or functions in metagenomes but is strictly reference based. Sometimes we do not want to classify every read, so, for taxonomic profiling, *MetaPhlAn2* comes in handy. Through mapping, it relies on an impressive and growing dataset of unique clade-specific marker genes identified from reference genomes for unambiguous taxonomic assignments for bacteria, archaea, eukaryotes and viruses and an accurate estimation of organismal relative abundance. For functional profiling, *MEGAN* can generate *KEGG* profiles of the whole metagenome, and the user can explore the detail of individual pathways of interest.

The annotation of a metagenome gives important information on the functions the microbial community is performing (Fig. 2). In this chapter, we will not cover deeply on the how-tos of genome annotation, however, two points are worth mentioning. The first is the existence of an inclusive pipeline that comprises several annotating tools: *Prokka*. *Prokka*, as its name indicates, has been developed to annotate prokaryotic genomes and it is not recommended to annotate eukaryotes. *Prokka* will predict coding sequences (CDS), rRNAs, tRNAs, signal peptides, and ncRNAs. For the CDS, it will use curated models of protein families from *UniProt*, *Pfams*, and *TIGRFAMs* to provide a better functional annotation of the genes. Finally, it will generate several output files including a fasta file with the predicted proteins and those necessary to submit your sequences to NCBI (gbk and gff). *Prokka* an accurate way to annotate your sequences; however, there are several other databases available for more specific annotation, such as *KEGG* for metabolism.

The second regards working with very large datasets, such as metagenomes. When sequence similarity searches are needed, *BLAST* can take considerable computational time. An accelerated *BLAST* alternative exists but comes with a price in sensitivity and accuracy. The *DIAMOND* (Double Index AlignMent of Next-generation sequencing Data) software performs pairwise alignment of proteins and translated DNA at 500–20,000× speed of *BLAST* and is explicitly designed to make use of modern computer architectures that have large memory capacity and many cores. When it is impossible to *BLAST* a metagenome, *DIAMOND* is the next best option.

Genome Resolved Metagenomics: Metagenome Assembled Genomes

Metagenomes have provided new means to resolve genomes without relying on cultivation. These “genomes” called Metagenome-Assembled Genomes (MAGs) can be recovered from the set of contigs present in our assemblies and have transformed our understanding of the tree of life. This approach aims at transitioning from billions of short reads into millions of contigs and finally thousands of MAGs. Note that MAGs represent the consensus genome from nearly identical cells present in the microbial community. Since these cells maintain slight genomic variations, the exact sequences of MAGs recovered from metagenomic assemblies do not necessarily exist in nature.

Due to limitations at several steps in current technology (sequencing, assembly, and recovery of MAGs), it is challenging to recover complete genomes from metagenomes. In most cases, the technique will provide access to incomplete genomes. In addition, it is a tough task to recover them without contamination (i.e., contigs belonging to another taxonomic lineage). We will briefly describe tools one could use to optimize the outcome of genome-resolved metagenomics while minimizing risks of contaminations.

Binning

Binning is the process of classifying some data and group it in several more or less continuous values into a smaller number of “bins.” We will refer to binning here, exclusively to classifying contigs out of the (co-)assemblies of metagenomes and bin them into MAGs. The goal is simple: solve a metagenomic puzzle by identifying contigs that belong to the same genome! In order to accurately classify our contigs, we rely on two independent properties: (i) sequence composition and (ii) differential coverage.

Genomes from different organisms possess different frequencies in tetranucleotide composition and GC-content. The tetranucleotide frequency (TNF) represents a genomic signature for each microbe, and genomic GC-content can range from 17% to 75%. These marked trends have enough power to classify contigs and bin them in broad categories. In fact, genomes were initially binned focusing on TNF, mainly with the *ESOM* (Emergent Self-Organizing Maps) software.

However, sequence composition alone lacks the resolution to distinguish between closely related microbes. These disadvantages can be overcome when we incorporate differential coverage to the binning process, taking advantage of the fact that abundance, and hence coverage, of each microbe differs in the microbial community. Comparing metagenomes from closely related sites, or from the same site at different time points allows us to exploit the property that different organisms exist in different abundances in the microbial community (differential coverage). Time series are ideal, as are sites close to each other. In addition, DNA extraction biases and the incubation of samples under different conditions can be used to take advantage of differential coverage.

Automatic binning software (e.g., *CONCOCT*, *MaxBin*, and *MetaBAT*) exploit these two properties to characterize bins from metagenomic assemblies and mapping results. Critically, automatic binning greatly vary in quality and the assessment of MAGs with SCGs is limited. Organizing and visualizing contigs in the context of biological (e.g., GC-content, TNF, taxonomical signal) and environmental information (mainly, the coverage of contigs across metagenomes and, if needed, individual nucleotides within a contig) can be used to manually curate MAGs and access their genome-wide quality. Such manual curation effort can be performed following the metagenomic binning workflow of *anvi'o*, which is described in the following section.

The *anvi'o* platform

Most bioinformatics processes we have described above for genome-resolved metagenomics have been integrated into the analysis and visualization platform *anvi'o*. *Anvi'o* allows either automatic or human-guided characterization of MAGs from metagenomic assemblies, with interactive interfaces that can link -omics data from multiple sources (e.g., DNA and RNA) into a single, intuitive display. Human-guided (a.k.a, manual) binning is time-consuming but recommended for quality purposes. Extensive web tutorials have been provided to describe the *anvi'o* programs (see <http://merenlab.org/>). In addition, international workshops are regularly organized so that the users can meet with the *anvi'o* developers and practice on reference datasets. Finally, users of the platform have formed an active slack community (<https://slackin-ezbpfhwsmh.now.sh/>) to help each other with technical and conceptual questions.

The *anvi'o* metagenomic workflow starts with (co-)assembly and mapping files, and the user will then be guided through the tutorials to annotate the metagenome and identify SCGs using HMMs. These SCGs provide the user with a rough estimation of how many bacterial, archaeal, and eukaryotic genomes are present in the assembly. Interestingly, this information can be used to determine how many clusters to automatically bin. *Anvi'o* incorporates all the information and properties of the assembly and combines it in a single display, allowing the user to explore the metagenomic assembly and its environmental signal interactively, and characterize and manually refine MAGs (a.k.a, the curation step).

Manual refinement of MAGs is an essential step to make sure we have a collection as flawless as possible for all our downstream genomic analyses, and for sharing them in the public databases. There is a guide on the Minimum Information of a Metagenome Assembled Genome (MIMAG) which classifies the MAGs into high-quality draft, medium-quality draft, and low-quality MAGs, based on the presence/absence of rRNAs, tRNAs, and on the levels of completion and redundancy of the MAGs. A perfect MAG would have every SCGs (100% completion) and only one copy of each of them (0% redundancy) or 100C/0R. While achieving this is some way off, MAGs with 90C/5R can be recovered using current techniques. Depending on our goals, we can afford low levels of completion up to 50%, but we don't want to reach the 10% redundancy cut-off due to contamination concerns.

Single-Cell Amplified Genomes

When Genome-Resolved Metagenomics is not enough to recover those genomes of the yet-unculturable and low abundant inhabitants of the community, single-cell approaches coupled with whole genome amplification and sequencing have already enabled the quantification of the heterogeneity in naturally occurring populations. The clearest example of this technological explosion is the recent accumulation of thousands of single-cell amplified genomes (SAGs) in databases like the IMG/M (3535 SAGs as of November 2018). Additionally, single-cell genomics is providing the opportunity to capture the total cellular DNA and thus associate chromosome and extrachromosomal elements, or cryptic endosymbiotic consortia as well as tight cell-cell interactions.

Single-cell experiments are a chain of challenging interdependent steps, from cell isolation to the recording of the downstream -omics or metabolic readouts. Main caveats include, but are not restricted to, maintaining the physiological conditions of unculturable/unknown microorganisms and reaching detectable levels of biological material while dealing with the omnipresent contamination.

Two flavors of single-cell isolation approaches are currently available: (i) free cells in continuous flow systems, which allow high throughput structural and/or metabolic differentiation of cell types based on their biochemical spectrum; (ii) confinement-based segregation, useful to study the effect of chemical/biological signals on cell growth, or when isolated cells need to be enriched for subsequent phenotypic measurements.

Further improvements in the field may lead to versatile technologies able to deliver sequence and metabolite measurements simultaneously for a large number of single-cells. This will help us to tease apart the complexity of microbiological networks and better predict their response to perturbations, undoubtedly triggering a new wave of targeted exploration of the metabolic and ecological networks mediated by microbial dark matter.

Pangenomics

In 2005, Tettelin et al. coined the term pangenome along with genome analyses of eight *Streptococcus agalactiae* strains. A pangenome is the union of the entire gene set known to exist in members of a group, typically in strains of the same species, or in members of a monophyletic clade. In order to define this "entire set" of genes, all genes in the selected genomes must be compared to each other to understand which genes are orthologous and group them together. There are several tools to cluster these orthologous genes in a given group of organisms. OrthoMCL has a web server, a database of orthologous protein sequences and command line-based software package that can be downloaded and used locally. Several online tutorials exist on how to use OrthoMCL. From a set of genomes, an all-against-all BLAST search of the proteins is performed. Putative orthologous relationships are identified between pairs of genomes by reciprocal best similarity pairs and a Markov Cluster (MCL) algorithm is employed to robustly cluster genes into orthologs, or "recent" paralogs from at least two species.

Once the grouping of the orthologous genes is performed, ad hoc scripts can be coded to extract the core genome of the pangenome, or alternatively, ITEP (Integrated Toolkit for Exploration of microbial Pan-genomes) can be used. The core genome usually refers to gene clusters identified in all (or most) genomes in the collection. These gene clusters commonly include ribosomal proteins and other housekeeping genes. It is also interesting to analyze the set of accessory genes, those genes that are specific to a subset of genomes. Genomes originating from organisms that share a particular trait (e.g., specific environment or stress) might possess accessory genes retained by selective pressure. Understanding the pangenome of a set of closely related organisms can also shed light on the evolutionary impact of HGT in the group.

The *anvi'o* platform includes a pipeline and tutorials to create pangenomes from reference genomes, newly characterized MAGs or a combination of the two sources. Notably, the platform allows visualization of the occurrence of thousands of gene clusters across the selected genomes, estimation of relationships between them based on gene clusters, computation and visualization of *average nucleotide identity scores*, and the linking of pangenomic traits with functional inferences.

The Universal Tree of Life

The amount and diversity of species with at least partial sequence information is rapidly increasing and the tree of life is constantly being redrawn. Phylogenetic trees represent a backbone of various biological studies and it is essential to have state-of-art tools for their display, customization, and interpretation. At your fingertips, an app available for Android and iPhone mobile phones, *Lifemap* developed by Damien de Vienne, allows you to locate (almost) any organism in a tree of life and calculate the distance to another one, drawing a route through possible common ancestors. Peer Bork's lab has an online tool, the *Interactive Tree of Life (iTOL)*, that allows you to explore precalculated phylogenies as well as displaying your own phylogenetic trees. Various types of data, such as genome size or protein domain repertoires, can be mapped onto the tree.

With the explosion of the metabarcoding techniques, an impressive collection of SSU genes has been made available. Now, metagenomics has unveiled a previously hidden biodiversity, obscured when viewed through the sole lens of metabarcoding. Some of these bacteria have introns in their rRNAs, making them invisible through amplification biased-techniques. Some other bacterial genomes lack some ribosomal proteins, which were thought to be part of the universal single-copy core collection of genes. All those bacteria and archaea that have long remained incognito, are now revealed through metagenomics and genome-resolved metagenomics. In 2016, Laura Hug et al. took advantage of MAGs to reconstruct a massive tree of life, changing of view of its topology with the incorporation of the Candidate Phyla Radiation (CPR) within the domain Bacteria.

It will take decades to fully appreciate the biological significance of MAGs affiliated to the CPR and other lineages with no cultured representatives. Without any doubt, all this unhidden diversity is revolutionizing the field once again and will outdate many aspects of this encyclopedia in its future editions. Indeed, now is an exciting time to explore the microbial world through bioinformatics!

Final Considerations

By routinely sequencing microbial communities and the genomes of those microbes that can be isolated (either by enrichments or by single-cell methodologies), scientists all over the world are contributing to an enormous collection of public genomic sequences. We can now compare microbial ecosystems from all over the world, from deserts to oceans, to skin microbiomes of frogs or humans to the New York subway. This huge volume of data is constantly challenging our concepts in Microbiology. In this past decade, our tree of life has expanded to unveil a large diversity of "Candidate Phyla," the metabolism and ecology of which we barely understand. We have also witnessed, thanks to genome-resolved metagenomics, the unmasking of an Archaeal lineage sister to the root of the Eukaryotes, shedding light on the possible last Eukaryotic common ancestor. The continuous flow of massive sequencing is continuously redefining our view of the world, we hope we have convinced the reader that computational tools and resources have been and will continue to be important for making such big contributions to the study of life.

Acknowledgments

We would like to thank all bioinformaticians contributing to the field of Microbial Ecology and Evolutionary Biology, including the *anvi'o* team. AGP is supported by European Research Council grant no. 322669 ProtistWorld and European Research Council grant no. 787904 Plast-Evol. PD is funded by the CNRS.

Glossary

Core genome Represents the genes present in all strains of a species. It typically includes housekeeping genes for cell growth and maintenance.

De novo Sequencing Sequencing a novel genome where there is no reference sequence available for alignment.

Draft genome An incomplete sequenced genome, with the possibility of missing nucleotides or segments.

Metagenome All the genetic material present in a sample consisting of all the genomes of the individual organisms in the environment.

Microbiome Collection of all the genomes of the microbes within a system or environment.

Microbiota Collection of microorganisms in a system or environment.

Next-generation DNA sequencing (NGS) DNA sequencing technologies that simultaneously determine the sequence of DNA bases from many thousands (or millions) of DNA templates in a single reaction.

Paired end sequencing Sequencing of both ends of the same fragment to generate alignable sequence data.

Pan genome The entire complement of genes representing all strains of a species.

Pseudogene A gene that has lost functionality due to a nucleotide point mutation, insertion or deletion.

Sequencing by synthesis The term used by Illumina to describe the base-by-base chemistry used in NGS machines.

SNP Single Nucleotide Polymorphism – a single base difference found when comparing the same DNA sequence from two different species.

Introduction

Genomic information has now become an almost essential component of microbiological and molecular biology research. Vast amounts of research and industrially-relevant genomic data is now publically available which undoubtedly increases our understanding of microbial genetics and host-microbe interactions. It is 22 years since the first microbial genome sequence of *Haemophilus influenzae* became available (Fleischmann et al., 1995) and 12 years since the advent of high throughput next generation sequencing (NGS) technologies which, in addition to sequencing bacterial genomes, has allowed the large accumulation of metagenomic data with many terabytes of sequencing data produced to date. With respect to DNA technologies, large progress has been made in terms of speed, read output, read length combined with a remarkable reduction in cost. This has allowed microbial genome sequencing to become a standard procedure and enables even the smallest of research groups to sequence their pathogen or organism of interest.

Genome sequencing, firstly can aid in the taxonomic classification in the study of an unknown organism. Additionally, access to even a basic draft genome with minimal annotation opens a wide range of opportunities and invaluable information on the genetic and metabolic capabilities of a microbe. A lack of accessible genomic data for a particular strain or species is now regarded as restrictive and the availability of such data is becoming a foundation for biological research and indeed increases overall research impact. In the instance where genomic information is existing for multiple strains of a species, extensive comparative genomics can be performed enabling core and even pan-genome analysis. Presently, the majority of bacterial phyla now have genome sequences available with many genera and species having multiple strains with full genomic data accessible. Additionally, there are over 20,000 metagenome projects accessible through repositories (Section 2) and although bacterial studies dominated initially, there is now also increasing interest in archaeal, viral and fungal communities (Section 4).

Recently, NGS has expanded past DNA genomics and is key to translating the research into practical applications such as in molecular diagnostics. In this article we focus on the availability and status of the many current sequencing technologies while providing a reference point to genomic repositories, databases and online resources. Additionally, we examine the impact of single genome sequencing on bacterial pathogenomics and probiotic research to date and finally we move beyond bacterial genomics and identify the key studies documented on viral, archaeal and fungal isolates.

Sequence Technologies and Online Resources

In the past 12 years, NGS technologies have been implemented in many applications, including whole genome sequencing, *de novo* assembly, metagenomics and transcriptome sequencing. NGS platforms perform massive parallel sequencing, during which millions of fragments of DNA are sequenced simultaneously. The technologies have advanced greatly since 454 Life technologies

This article is a reprint of Caitriona M. Guinane, Michael J. Callanan, Genome Sequencing of Microbes, *Reference Module in Life Sciences*, Elsevier, 2018.

launched the first commercial next generation sequencer in 2005 which at that time could sequence a read length of 100–150 bp with an output of 20 Mb per run (Margulies et al., 2005). The 454 technology, developed by Roche, did improve from this and achieved approximately 1 million reads with read lengths of more than 700 bp in with the FLX+ system and data processing with outputs of up to 70 Mb with the bench top sequencer, the GS Junior in 2009. However, newer sequencing technologies emerged that could provide longer read lengths or a greater number of reads at a much lower cost which led to a move away from this technology and 454 sequencing was no longer available from mid-2016. NGS technologies past and present, including their sample preparations have described in many other reviews (Liu et al., 2012; Buermans and den Dunnen, 2014; Guinane et al., 2016; Mardis, 2017) so this article just briefly discusses the recently released technologies.

Current Sequencing Platforms

The choice of technology for a microbial sequencing project largely depends on the desired application; whether it is *de-novo* genomic sequencing by paired-end sequencing or resequencing by whole-genome shotgun strategies, compositional analysis from a large bacterial community or RNA-seq data from whole transcriptome data the strategy for sequencing will vary or perhaps require a combination of the technologies outlined below.

There are a number of different companies currently commercially active in the sequencing area. Qiagen (see Relevant Website section), a recent addition to the sequencing market, provides a complete NGS workflow on their recently launched GeneReader platform, however this is specifically designed for cancer biology rather than microbial genomes and therefore is outside the subject area of this article. Illumina, operating DNA sequencers since 2008, offers a range of sequencers adopting clonal amplification and the sequencing by synthesis (SBS) technology. Within its sequencing platform repertoire, Illumina offers bench top sequencing systems (MiniSeq, MiSeq and NextSeq series) in addition to large production scale sequencers (HiSeq, HiSeqX and NovaSeq series). The MiSeq is the most established benchtop sequencer with a run time of just 4 h and an output of up to 25 million reads intended for targeted sequencing and for the sequencing of small genomes. The newest bench top sequencer launched in 2016, the MiniSeq allows for small scale targeted sequencing projects and is aimed at affordable sequencing for a smaller lab group. The MiniSeq can achieve read lengths of 100–150 bp and an output of ~7 Gb (see Relevant Website section). At a larger scale, Illumina supply the HiSeq 2500 and the HiSeq X 10, which together can each achieve an output of up to 600 Gb/day. The most recent addition to the sequencer repertoire is the NovaSeq series consisting of the NovaSeq5000 and the NovaSeq6000. These are cloud-integrated instruments and claim to provide access to powerful, high-throughput genomics at a lower price (see Relevant Website section).

Thermo Fisher Scientific (previously owned by Life Technologies) also provide a range of sequencers based on ion semiconductor sequencing which relies on the detection of hydrogen ions released during the sequencing process (Rothberg et al., 2011; see Relevant Website section). Bench top sequencers provided include the Ion Torrent Personal Genome Machine (PGM) and the Ion Torrent Proton released in 2010 and 2012 respectively. Ion technology has evolved very quickly which has allowed both machines to increase in read lengths and in data output (Buermans and den Dunnen, 2014). Many options are available for varying applications. The PGM, for example can provide reads up to 400 bp and therefore useful for targeted resequencing of small genomes. The Proton however generates shorter reads and therefore useful for applications such as RNA-seq transcriptomics. Due to the quick speeds of ion technology (2–8 h run times) these machines are potentially suitable for molecular diagnostics and other applications in a clinical setting (Mellmann et al., 2011).

Other sequencing technologies in, as yet, limited use include “third generation sequencers” named as such due to the fact that the technologies involve single molecule detection and the signal is captured in real time. Available platforms for these technologies include the Pacific Biosciences Single Molecule Real-Time (SMRT) system and the Oxford Nanopore system. Pacific Biosciences SMRT system is based on the properties of zero-mode waveguides and signals are generated in the form of light signals (reviewed in Buermans and den Dunnen (2014), Liu et al. (2012)). The PacBio RS instrument generates several thousands of up-to-several-kilobase long reads ideal for *de novo* genome sequencing, however has been documented to have a high base error rate (Rhoads and Au, 2015). DNA sequencing using Nanopore technology was first introduced by Oxford Nanopore Technologies in 2014. The basic principle of Nanopore DNA sequencing involves the passing of an ionic current through a pore and measuring the current changes as the biological molecule passes through (Wang et al., 2014). The MinION was the first instrument launched by the company in 2015 in the form of a handheld portable device. This instrument also is low cost and can generate ultra-long reads (>100 kb) however high error rates have been documented for the MinION and although long read lengths are indeed achievable, low overall mean and median lengths have been reported on initial instruments (Laver et al., 2015). The company also recently launched the GridION X5 which can hold 5 MinION flow cells on a single bench top machine and a newly described PromethION which proposes sites for 48 flow cells promising industrial scale level of sequencing (see Relevant Website section). Other companies that provide promise in “third generation” sequencing include Roche which were one of the first companies active in next generation sequencing. Roche are also developing a nanopore-based platform for single molecule detection (see Relevant Website section). Quantum Biosystems, a relatively new company are developing a single-molecule electronic DNA sequencing technology that measures currents from DNA bases as the molecule passes by a sub-nanometer gap (see Relevant Website section).

Computational Challenges

The expansion in DNA sequencing technologies has indeed revolutionised biological research. However in creating vast amounts of raw sequence datasets, it has led to many bioinformatic challenges. Although the time taken for DNA sequencing has reduced

dramatically, there is still much time, difficulty and cost associated with the storage and analysis of the raw sequence reads. Scientists need to store, share and analyse vast amounts of datasets which require specialist computational skills. For single genome sequencing of a microbe, the raw read output from sequencers need to be quality checked and then assembled into contigs and scaffolds for feasible analysis of the genetic content. The software capable of performing many of these tasks are available on Linux-based operating systems demanding specific bioinformatics skills for competent use. Following genome assembly, it is then necessary to extract all the most valuable information from the sequence data, which involves gene prediction and functional annotation. Manual annotation can be a laborious and a time-consuming procedure. In fact the majority of genomes now available in Genbank are in draft format and not fully completed genomes due to the high volume of sequence data for microbial genomes currently being generated. There has, however, been many computational developments in this area in recent years and there are now many user-friendly software programs to assist in genome sequence analysis as outlined in the following section.

Genomic Repositories and Online Sequence Tools

In recent years, databases and online tools are playing a significant role in biology and are central to microbial genomic research. There are a number of data repositories for the storage and retrieval of biological data with the National Centre for Biotechnology Information (NCBI) and the European Molecular Biology Laboratory/European Bioinformatics Institute (EMBL-EBI) being the primary resources available that hold genomic collections. It is now mandatory to deposit all genome sequence data from any published genome project. Nucleotide sequence submissions can be made to any of the 3 databases; the DNA data bank of Japan (DDBJ), GenBank (USA) and the European Nucleotide Archive (Europe). These exchange data on a daily basis to ensure management between them and all nucleotide sequence data from all organisms is accessible from any of the databases. These are primary repositories, as they hold the original sequence data. These collaborate with the Sequence Read Archive (SRA), which stores raw reads from high-throughput instruments including metagenomic and compositional raw sequencing data.

In addition to the above tools there are also other resources that allow the integration of genomic and molecular biology data retrievable for further bioinformatic analysis. Examples of the main resources used by the research community include the Genomes on line database (GOLD) (see Relevant Website section) which integrates global genomic, metagenomic and associated metadata, the IMG/M: Integrated Microbial Genomes & Microbiomes (Markowitz et al., 2012a,b) the Microbial Genome Database (MBGD) (Uchiyama, 2003), the SEED viewer (Overbeek et al., 2014) which allows gene prediction and functional annotation and the MicrobesOnline (Dehal et al., 2010) resource that in addition to the availability of genomic data allows comparative genomic analysis and gene expression analysis. Databases specific to a particular pathogen are also available which allow in-depth analysis of an organism such as Fusobase (Ang et al., 2014) that provides genomic data for multiple strains and species of the emerging human pathogen *Fusobacterium* spp. and GenoList (Lechat et al., 2008) which allows multi-strain analysis of *Listeria* spp. There are also specialised databases that allow the detection of antibiotic resistance genes such as the comprehensive antibiotic resistance database (CARD) (McArthur et al., 2013) or to a particular strain trait such as antimicrobial peptide production including as Bagel 3 (van Heel et al., 2013) and antismash (Blin et al., 2017). Additionally, special purpose resources for specific functional gene analysis include STRING (see Relevant Website section) for protein-protein interactions, the CDD (see Relevant Website section) for conserved domain analysis, and Pfam (see Relevant Website section) and SMART (see Relevant Website section) for protein family analysis and the Clusters of Orthologous Groups of Proteins (COGs) database (Tatusov et al., 2003) for the phylogenetic classification of proteins. Further information on available resources for microbial genomic analysis is documented by Zhulin (2015).

Catalogue of the Human Microbiome

Over the last 10 years, a number of research consortia have generated large amounts of sequence data of microbes with a vast array of accompanying online resources for data access and analysis. Data relating to microbial diversity, deposited metagenomic projects and reference genome collections from the human microbiome are now easily accessible. Large scale consortiums such as the EU-funded MetaHIT (Metagenomics of the Human Intestinal Tract) (Ehrlich et al., 2011) studied associations between the genes of the human intestinal microbiota and our health focusing on two specific disorders, Inflammatory Bowel Disease (IBD) and obesity (see Relevant Website section). The National Institutes of Health Common Fund Human Microbiome Project (HMP) was established in 2008, with the objective to characterise the human microbiome to understand its role in human health and disease (see Relevant Website section). The initial phase of the HMP resulted in the sequencing of 3055 reference microbial genomes from multiple body sites and included 1265 metagenomic projects. The second phase of the HMP aims to integrate datasets from the microbiome and the human host from specific studies of microbiome associated conditions such as IBD and type 2 diabetes (see Relevant Website section). An example of a database specific to one body site is the Human Oral Microbiome Database (HOMD) which provides sequence data and taxonomic information on ~700 prokaryote species that are present in the human oral cavity (Chen et al., 2010).

Overall these catalogues provide the biological research community access to the human microbiota furthering our understanding of these communities can impact on human health and disease. It is now possible to retrieve metagenomic, metatranscriptomic, human genetic, microbial culture, and many other data types from each project.

Understanding Bacterial Genomes

Our understanding of bacterial virulence and evolution has significantly improved with the sequencing of pathogen genomes. Since the first bacterial genome was sequenced over 20 years ago, there are now almost 2000 bacterial genomes fully sequenced including many strains of important clinical pathogens such as *E. coli* O157:H7, *Listeria monocytogenes*, Methicillin-resistant *Staphylococcus aureus*, *Mycobacterium tuberculosis* and *Clostridium difficile*.

The advent of DNA sequencing of microbes has provided significant understanding into the genetic mechanisms underpinning pathogenicity and evolution, the epidemiology of bacterial pathogens and provides a possible option of rapid detection and monitoring of outbreaks (Fig. 1). The improved resolution at nucleotide level provided by whole genome sequencing (WGS) has provided critical insight for determining the appropriate response to an infection. In disease progression, the ability to obtain detailed information on the pathogenic microbe from multiple patients or even multiple isolates from a single patient is extremely attractive. The reduction in sequencing cost has put WGS in scope of routine analysis in research and even clinical microbiological settings. There are comprehensive reviews (Bentley and Parkhill, 2015; Klemm and Dougan, 2016; Land et al., 2015) that have addressed this area, therefore here we outline just some examples of what we have learned from sequencing of pathogen genomes to date.

Architecture of the Pathogen Genome

The availability of complete genome sequence data from microbial pathogens has provided insights into key virulence genetic systems. Notably, studies have elucidated the evolution and function of bacterial protein secretion systems and protein-targeting mechanisms, such as sortases, which enable the attachment of substrate proteins including enzymes, pilins and adhesins to the bacterial cell surface (Loman and Pallen, 2015). The study of bacterial pathogens using traditional approaches identified many factors such as toxins, adhesins and invasins that are prerequisites to the development of pathogenicity and are often based on the acquisition of specific genetic elements. However, prior to WGS these genes and systems were studied largely independently of the complete genomic make-up of the microbe. Given the importance to human health, unsurprisingly the first microorganism whose complete genome was sequenced was a pathogen, *H. influenzae* (Fleischmann et al., 1995). In addition to colonizing the nasopharynxes of healthy humans, *H. influenzae* causes acute respiratory infections in addition to invasive bloodstream infections such as meningitis and cellulitis. In common with many of the first complete genome sequences, a key finding was that 42% of the predicted coding regions did not have homologue or putative function assigned. In fact the results from the first completed

Fig. 1 The impact and possibilities of microbial genome sequencing on pathogen, probiotic and clinical research.

prokaryotic genome sequences showed that almost half of predicted coding regions identified were of unknown biological function (Fraser *et al.*, 2000). Moreover, at the very early stage of genome sequencing approximately 25% of all predicted coding sequences in each species were found to be novel.

Early studies on strains of the same species centred on *Escherichia coli*. Comparisons between a highly pathogenic strain of *E. coli* O157:H7 and the *E. coli* K12 type strain revealed that over a quarter of the genes (26%) were unique to the pathogen compared with the type strain (Perna *et al.*, 2001). It was known that the pathogenicity was largely associated with the gain or loss of genetic material through various mobile genetic element but the scale of the differentiation was unexpected. Further comparative genomic studies confirmed the earlier observations of substantial diversity within an individual bacterial species. For example, differences in 25% of the gene content was also observed amongst strains of *Neisseria meningitidis* and *Helicobacter pylori* (Boucher *et al.*, 2001). Individual isolates contained very large numbers of unique genes and an increasingly small number of genes were observed in all members of any one species. The idea of the pan genome (representing all the genes in a species) subsequently emerged where species have a central core genome responsible for cell maintenance and regulation found in all strains and an accessory or more “expendable” set of genes that differ among the strains of a species (Medini *et al.*, 2005). The *E. coli* species, as indicated from the initial studies, is an example of a genetically diverse organism with an extensive pan genome content. Recent comparisons of more than 2000 *E. coli* genomes revealed a core genome of more than 3000 gene families with a total of ~89,000 different gene families existing in the overall pan genome (Land *et al.*, 2015). This level of diversity means in any one *E. coli* genome (~5 Mb), up to one third of each genome is part of the accessory genome and not present in all strains (Land *et al.*, 2015).

In contrast to the diversity observed in *E. coli* genomes, comparative genomics has revealed that other human pathogens such as *Salmonella typhi*, *Yersinia pestis* and *Bordetella pertussis* demonstrate a high degree of ‘celibacy’ with little mobile DNA and limited genetic diversity (Parkhill *et al.*, 2001a,b, 2003); reviewed by Bentley and Parkhill (2015). Genomic analysis of these pathogens identified many similar characteristics with a large amount of repetitive DNA and a high number of pseudogenes. Despite these organisms being successful pathogens many pseudogenes, surprisingly, appeared to be non-functional genes previously involved in virulence or host interactions. Also a common feature was that these organisms occupied an acquired restricted niche and are likely to have evolved to adapt to their environment. *Y. pestis* for example displayed 150 pseudogenes which were indicative of a redundant gastrointestinal organism but had gained the genetic determinants for life as a systemic invasive pathogen (Parkhill *et al.*, 2001b).

It has become clear that we have learned that the genome structure varies greatly among species. Some organisms are extremely diverse and heterogeneous varying considerable in size and gene content whereas others show much conservation and limited genetic diversity. This knowledge is instrumental in developing strategies to deal with detection and control of these microbes.

Global Epidemiology and Transmission Mapping

The arrival of high-throughput DNA sequencing has also widely facilitated SNP-based phylogenetic analyses of bacterial pathogens enabling transmission mapping of pathogens and disease outbreaks (reviewed by Bentley and Parkhill (2015), Klemm and Dougan (2016)). The links between genomic diversity and geography have been studied for pathogens such as *Salmonella enterica* serovar Typhi (Typhi), the causative agent of Typhoid fever. As mentioned above, Typhi shows limited diversity among isolates with overall high conservation of genetic content. With such low levels of variation, the availability of whole genome sequences has impacted greatly on epidemiological studies. Holt *et al.*, performed an early study on multiple pathogen isolates generating 19 Typhi whole genome sequences using a combination of NGS technologies (454 and Illumina). This intraspecies comparison study indicated large scale loss of gene function among isolates and limited evidence for recombination events indicating a small population was causing genetic drift of typhoid across the world (Holt *et al.*, 2008).

An excellent example of where bacterial genomic analysis has been instrumental in deciphering the evolution and epidemiology is that of *Vibrio cholerae*. Cholera, an acute diarrheal infection, is a global threat to public health with previous epidemic dynamics poorly understood. Recent population genomic studies however have brought significant new understanding of the evolution and long-range spread of the causative agent, *V. cholerae*. The current ongoing seventh cholera pandemic began in Indonesia in 1961 and spread through Asia to Africa, Europe, and Latin America. This pandemic is caused by a new biotype of *V. cholerae* first isolated in 1905 in El Tor, Egypt (Sack *et al.*, 2004). Genomic analysis by a number of authors showed that the El Tor lineage had emerged from the environmental reservoir of *V. cholerae* independent of lineage responsible for the first six pandemics (Robins and Mekalanos, 2014; Heidelberg *et al.*, 2000). Further genomic analysis of isolates from the seventh pandemic allowed phylogenetic analysis of the El Tor lineage which demonstrated an evolutionary relationship between strains (Mutreja *et al.*, 2011). Following genomic, SNP and phylogenetic analysis it enabled the authors to pinpoint the origin of the seventh pandemic clone concluding it most likely had originated from a single region in the Bay of Bengal and from there spread worldwide (Mutreja *et al.*, 2011).

The availability of genome sequences was also pivotal to tracing the origins of the *E. coli* strain causing an outbreak of diarrhoea and Hemolytic-Uremic Syndrome in Germany. In the study by Rasko *et al.*, third generation sequencing was used to determine the sequence of a number of *E. coli* strains including the outbreak strain (Rasko *et al.*, 2011). Largely influential in transmission mapping and pathogen detection of the *E. coli* serotype involved was the rapid high throughput bench top sequencing performed, the open source availability of the sequence data and the outsourcing of data analysis to expert computational biologists (Rohde *et al.*, 2011). In a logical extension of this application to a foodborne outbreak, the USDA have created the GenomeTrakr network (see Relevant Website section) which is the first distributed network of laboratories to utilize WGS for pathogen identification due to its superior resolution over conventional typing techniques. It has input from a number of public health and university

laboratories that collect and share all genomic and epidemiological data from foodborne pathogens which is then accessible by researchers and public health officials.

Clinical Applications

DNA sequencing technologies have much potential in clinical microbiology to detect microbes leading to the potential rapid diagnosis of infectious diseases. It could be extremely advantageous in the identification of certain bacterial and fungal organisms which grow slowly and require species-specific growth conditions. Some organisms can take days to culture possibly leading to a delay in the appropriate antimicrobial therapy being used. Within a clinical setting, initial bacterial population genomic studies focused on the pathogen *S. aureus*. Harris *et al.*, demonstrated WGS data was able to provide the resolution required to differentiate clonal isolates of *S. aureus* within a single hospital ward (Harris *et al.*, 2010). Further work then showed that combining WGS with data from epidemiology studies enabled reconstruction of a hospital outbreak of Methicillin Resistance *S. aureus* (MRSA) from a special care baby unit identifying a persistent outbreak and transmission of infection into the community. WGS allowed the confirmation of MRSA carriage by a hospital staff member which assisted in maintaining the outbreak (Harris *et al.*, 2013). A more recent study, again showed, genomics being used successfully to identify outbreak strains in a hospital-acquired infection of MRSA in China (Kong *et al.*, 2016).

The availability of bacterial genomes has also given insight in to the pathogen evolution during patient infection and colonisation over time (reviewed by Didelot *et al.* (2016)). A critical area where WGS has provided important insights is the evolution of within-host antibiotic resistance. An example of this application was demonstrated through the genome sequencing from *Mycobacterium tuberculosis* isolates from a single patient revealing nucleotide substitutions responsible for rapid antibiotic resistance development. From a single patient over a period of just 3.5 years, the evolution of an extremely drug resistant *M. tuberculosis* isolate from a drug-sensitive strain was demonstrated (Eldholm *et al.*, 2014).

WGS represents a molecular method that could be used to predict antibiotic resistance, assess virulence and genetically identify and type isolates. The possibilities of NGS as an effective diagnostic tool is an exciting prospect and would be particularly advantageous in the instance where an infecting microbe is not easy to culture. An increasing understanding of the capabilities of microbial genome sequencing is pivotal to its implementation into clinical medicine and in public health surveillance (Weinstock *et al.*, 2016). For full application and routine use, however, many challenges have to be addressed. A regulatory framework for NGS technologies in clinical medicine needs to be implemented, in addition to a dedicated and standardised reference genomic database. Furthermore, operational hurdles need to be overcome such as user friendly bioinformatic software and computational expertise needs to match the technical ability of the sequencers to fully use and interpret the data outputs.

Genome Sequencing of Probiotics

As outlined above, initial efforts in bacterial genome sequencing concentrated on pathogen genomes as researchers sought to determine the genetic determinants for virulence and antibiotic resistance. A growing research area now however is the sequencing of microbes that are beneficial to human health to understand the genetic determinants for potential probiotic traits and subsequently for functional food strain selection (reviewed by Guinane *et al.* (2016)). To date, putative probiotic strains with an available genome sequence are those associated with the gut microbiome and confer a health benefit. Leading probiotics that are currently commercially available generally come from the 2 genera; *Bifidobacterium* and *Lactobacillus*. The first genome sequences for probiotic strains available were of *Lactobacillus plantarum* WCFS1 (Kleerebezem *et al.*, 2003), *Lactobacillus johnsonii* NCC533 (Pridmore *et al.*, 2004), *Lactobacillus acidophilus* NCFM (Altermann *et al.*, 2005) and *Bifidobacterium longum* NCC2705 (Schell *et al.*, 2002). Since these early genome sequencing projects, the probiogenomics area has grown rapidly with many species of *Bifidobacterium* (*B. longum*, *Bifidobacterium breve*, *Bifidobacterium catenulatum*, *Bifidobacterium animalis*) and *Lactobacillus* (*L. acidophilus*, *L. plantarum*, *L. johnsonii*, *Lactobacillus casei*, *Lactobacillus paracasei*) with multiple complete genomes available and numerous more in draft (see Relevant Website section). The genomics revolution and sequencing of the human microbiome has led to the discovery of many of other species that have probiotic potential now being called “next generation probiotics” expanding the likelihood of more live biotherapeutic products. There are many available complete genome sequences for strains of these proposed beneficial bacteria including *Faecalibacterium prausnitzii* (Heinken *et al.*, 2014), *Akkermansia muciniphila* (van Passel *et al.*, 2011), and draft genomes for strains of *Eubacterium hallii* considered a promising bacterium for maintaining intestinal metabolic balance due to its substrate utilisation spectrum (Duncan *et al.*, 2004). High throughput sequencing technologies allows putative probiotics to be fully studied for potential health benefits and also for determining the safety of an organism at a genetic level to ensure the absence of transferable antibiotic resistance loci or virulent genes.

Current Developments in “Non-Bacterial” Sequencing

Although bacterial genome projects tend to dominate, high throughput sequencing has also revolutionised viral, fungal and archaeal research. The large diversity of the microbial world (ie small size of viruses compared to the large and complex genomes of a yeast) leads to the different sequencing technologies required depending on the required read length and depth of sequencing necessary. Each group has their own limitations which are very briefly discussed below.

Viruses, specifically have genomes much smaller than bacterial cells and therefore are obvious candidates for NGS technologies. Viruses are extremely genetically diverse and rapidly evolving with an explosion in the number of available viral genome sequences in recent years. NGS has become extremely important in overall viral research and in virus detection in a clinical setting. Difficulties in sequencing however can arise due to the very small size of some viruses or due to host contamination of viral nucleic acid (Marston et al., 2013) and as many virus are composed of RNA they are not detected by metagenomic DNA sequencing. Additionally, for clinical application, an enrichment step is often necessary to detect viral populations present in lower numbers (Datta et al., 2015). In recent years, many advances in genomic research has enabled analyses of the viral communities living within human body which are collectively called the human virome. The virome is particularly extensive and includes viruses that can invade and infect human cells, viral derived elements and bacteriophages that as yet remains relatively uncharacterised. However as sensitivities improve their impact within the human microbiome is likely to be determined.

Sequencing of archaeal genomes have also gained much attention and indeed the first Archaeon genome sequence, *Methanococcus jannaschii* was released in 1996 just one year after the first bacterial genome (Bult et al., 1996). The *M. jannaschii* genome enabled biologists to study prokaryotic evolution but also provided much insight in to archaeal biochemical and enzymatic pathways (Garrett, 1996). Subsequently there was much interest in archaeal genomes for evolutionary analysis and many formed part of the GEBA project: 'Genomic Encyclopedia of Bacteria and Archaea' (Wu et al., 2009). To date there are over 150 complete genomes available for Archaeal species (see Relevant Website section). Additionally, although receiving a lot less attention than their bacterial counterparts, a small number of archaeal genera have been identified in the healthy human microbiome, primarily in the gut with the species with *Methanobrevibacter smithii* being the best documented and most widely studied (Lurie-Weinberger and Gophna, 2015).

Fungi are a large group of eukaryotic organisms that ranges from yeast and moulds to mushrooms. As a large and diverse family, fungi are extremely important in human health and disease in addition to having a large role in many areas of biotechnology. The first fungal genome of the model yeast *Saccharomyces cerevisiae* was sequenced in 1996 (Goffeau et al., 1996). This genome was just over 12 Mb, however the size of fungal genomes can vary from just under 9 Mb to 177.57 Mb. Until recently, fungal genomes did not dominate the genome repositories and due to the genetic diversity within this group a lack of genetic knowledge was apparent. However an initiative by the JGI is quickly changing this and bridging the gap with the 1000 fungal genome project. To date there have been more than 800 genomes made available by the JGI mycocosm resource (see Relevant Website section). The fungal components of our resident microbiota, collectively known as the human mycobiome, also remain somewhat undiscovered to date. However, due to their predicted involvement in a number of GI diseases, the gut mycobiome have begun to receive increasing research interest. The advances in HGS technologies has permitted in depth analysis of the mycobiome allowing a move away from the traditional culture based approaches. Optimisation of DNA extraction techniques and primer development are current priorities to sample the mycobiome efficiently. In recent years, there are more and more studies that have been performed which has surveyed the mycobiome in healthy patients and in disease states (for review see Huseyin et al. (2017)).

Future Perspectives

The development of high-throughput sequencing technologies has enabled microbial genomes to be sequenced in a matter of hours while metagenomic studies have transformed our ability to determine the composition of complex microbial communities. As outlined in this article, there are many sequencing platforms available to choose from a plethora online resources for bioinformatic analysis. Whole genome sequencing has permitted the full genetic information to be determined on all domains of microbial life including pathogenic and probiotic microorganisms allowing us to understand how they function in health and disease. With the advances in technologies and the reduction in sequencing costs, the use of WGS can potentially revolutionise clinical microbiology, biosurveillance and molecular diagnostics. The ability to replace time consuming and labour intensive techniques is very tempting. Rapid identification of pathogenic microbes without the need to wait for traditional culturing methods, determining the existence of antibiotic resistant clones, the ability to trace food-borne outbreaks are just some examples of uses of sequencing in food safety and biomedicine. There is no doubting the huge impact that NGS technologies have had on microbial and molecular research and demonstrates much future potential for routine application in commercial and clinical settings.

Genomes From Uncultivated Microorganisms

Tanja Woyke, Devin FR Doud, and Emiley A Elie-Fadrosh, DOE Joint Genome Institute, Walnut Creek, CA, United States

A Brief History of Microbial Genomics

In 1995, the first complete genome of a free-living microorganism, that of the bacterium *Haemophilus influenzae*, was sequenced by J. C. Venter and colleagues. This achievement proved the utility of shotgun genome sequencing and the discipline of microbial genomics was born. The years that followed were marked by sequencing genomes of bacterial and archaeal cultured isolates, and nearly 25 years later, well over 90,000 bacterial and nearly 900 archaeal isolate genome sequences are available in the public domain (Fig. 1). Due to our inability to cultivate the majority of microorganisms, cultivation-independent approaches to microbial genome discovery and identification, namely metagenomic sequencing, came to light in 2004 (Tyson et al., 2004; Venter et al., 2004) and have since been incredibly popular. Initially, cultivation-independent approaches were necessarily restricted to gene-centric analyses unless the microbial diversity of the sampled environment was very low; however, in recent years, genome-resolved metagenomics has become feasible through advances in sequencing technologies, metagenome assembly, and, importantly, computational binning algorithms (Wrighton et al., 2012; Albertsen et al., 2013). Genome-resolved metagenomics provides clear links between phylogeny and function, and offers population-level information on genome variability.

Complementary to genome-resolved metagenomics is microbial single-cell genomics, the sequencing of the genome from an individual cell directly isolated from the environment (for a review, see (Woyke et al., 2017)). Single-cell genomics emerged in 2005 when A. Raghunathan and colleagues demonstrated that sequence data from a single *Escherichia coli* cell could be obtained. Two years later the first genomes were recovered from the candidate phylum Saccharibacteria (formerly TM7) using single-cell sequencing. Since then, single-cell genomics methods have been widely adopted to complement metagenomics. To date, more than 5,000 bacterial and archaeal single amplified genomes (SAGs) and nearly 13,000 metagenome-assembled genomes (MAGs) from bacteria and archaea are in the public domain (Fig. 1). These genomes provide a rich resource for the phylogenetic and functional interrogation of the uncultivated majority within the tree of life.

Technical Aspects for Accessing Genomes From Uncultivated Microorganisms

Genome-Resolved Metagenomics

The term 'metagenomics' was coined in 1998 by J. Handelsman and colleagues to describe an approach for exploring phylogenetic and functional diversity by directly extracting and cloning environmental DNA. The basic experimental methodologies have remained stable, while the field has seen major advances in high-throughput sequencing technologies and downstream computational analyses. Mechanical or chemical lysis approaches are used to extract total nucleic acids from cells from a given environmental sample (Fig. 2). Extensive literature exists detailing impacts of sample preservation protocols, microbial biomass considerations, DNA extraction methodologies, and contamination considerations (for a review, see Quince et al., 2017). Based on sample quantification, subsequent library preparation approaches are predominantly geared towards sequencing on the Illumina platform. These library preparation methods include transposase-based 'tagmentation,' used in the Illumina Nextera and Nextera XT products, and PCR-free methods relying on physical fragmentation, used for Illumina TruSeq preparations. Known biases based on library preparation methods and the number of PCR cycles have been documented and are known to impact taxonomic abundance profile calculations. Increasing sequence output by leveraging the newly released Illumina NovaSeq platform promises upwards of 6 Tb in a dual flow cell run, enabling even deeper sequencing of environmental samples.

Fig. 1 The number of microbial isolate genomes, single amplified genomes (SAGs), and metagenome-assembled genomes (MAGs) sequenced over time. Data were extracted from the Genomes OnLine Database (GOLD; <https://gold.jgi.doe.gov>) on 11/21/2017.

Fig. 2 Workflow for laboratory and analysis approaches of single-cell genomics and genome-resolved metagenomics.

Single-molecule long read sequencing technologies, including Oxford Nanopore and Pacific Biosciences, hold potential for metagenomic applications, yet are not widely utilized because it is challenging to extract high-quality, high molecular weight DNA. Alternatives to true single molecule sequencing generate ‘synthetic long reads’ from barcoded short reads or apply high-throughput chromosome conformation capture (Hi-C) technology. These and other technological developments on the horizon will undoubtedly shift the current paradigm of genome-resolved metagenomics away from computationally intense short-read assembly dependencies. For instance, a recently described novel approach from J. Beaulaurier and colleagues utilizes DNA methylation signatures derived from single-molecule real-time sequencing to resolve species- and strain-level bins, as well as link mobile genetic elements such as plasmids to their host.

Two avenues for computational analyses can be pursued with short-read shotgun metagenomics, namely *de novo* metagenome assembly and assembly-free metagenomic profiling to estimate taxonomic abundances. Here, we focus on *de novo* metagenome assembly as this approach enables subsequent reconstruction of population genomes to enable genome-resolved metagenomics. The de Bruijn graph approach underpins the majority of current metagenome assembly algorithms, although at present, there is no community consensus as to which assembly method is superior (Quince et al., 2017). While significant improvements in metagenome assembly workflows have been made, challenges remain for highly complex environments that consist of hundreds to thousands of strains.

To resolve metagenome-assembled genomes, termed MAGs, methods to link contigs to their respective genomes – termed binning – are required post-assembly. Binning methods can exploit sequence composition, species abundance, chromosome organization, or other inherent properties of the shotgun metagenomic data. A myriad of binning tools and approaches are available; however all tools are currently limited in their ability to distinguish closely related species and strains. Lastly, MAGs

are evaluated for estimated genome completeness and contamination using universal single copy genes. As can be observed in Fig. 1, the deposition of MAGs within public databases has proliferated in the last three years and has led to major scientific insights.

Single-Cell Genomics

Although the overall approach to single-cell genomics is rather simple (Fig. 2), several technical aspects should be considered when generating and analyzing genomes from individual environmental cells. On the experimental side, sample preparation, cell isolation, cell lysis and whole genome amplification are critical steps in the procedure (Rinke et al., 2014). Unless fresh samples are available for immediate processing, cryopreservation of the sample material using cryoprotectants such as glycerol, betaine, or DMSO is important to minimize cell damage and maximize maintenance of the integrity of the cellular structure and the genomic DNA. Further, samples should be prepared so that cells are well dispersed, facilitating efficient single-cell isolation. Although various methods are available for this next step (for a review see (Blainey, 2013)), including micromanipulation and microfluidics, fluorescence-activated cell sorting (FACS) has been used most prevalently by flow-sorting cells based on their size and level of fluorescence (stain-based or autofluorescence). A chief advantage of FACS is its accuracy and speed and thus high throughput. Following isolation, cells are lysed to make DNA accessible to whole genome amplification (WGA). To date, no universal lysis method exists and each sample may require custom adjustments based on the target taxa of interest. Most commonly used methods include alkaline lysis, though chemical lysis has more recently been combined with physical (i.e., freeze-thawing) and enzymatic (i.e., lysozyme treatment) lysis (Blainey, 2013; Rinke et al., 2014). Despite the continued development of a broad range of WGA methods (for a review, see (Blainey, 2013)), Phi29-mediated multiple displacement amplification (MDA) has remained the key technique used for microbial single-cell sequencing. Recently, a thermostable Phi29 polymerase mutant was shown by Stepanauskas and colleagues to yield improved genome recovery for single cells with high GC genomes. Both enzymes are strand-displacement polymerases with high processivity that rely on random hexamers to prime the reaction before amplifying long (>10 kb) DNA products to generate the SAG. Taxonomic identification of SAGs can be performed via direct PCR amplification and Sanger-based sequencing of the small subunit (SSU) rRNA gene. Illumina's Nextera protocol is recommended for generating the shotgun sequencing library because it minimizes sample handling, and thus cross-contamination, and reduces cost. For SAG sequencing, the Illumina NextSeq platform has proven most useful, as bleed-over between poolmates is minimal and short reads/ short insert libraries minimize the occurrence of chimeric reads or read pairs, which hamper the sequence assembly process (see following section for more details).

Genome amplification causes single-cell sequence data to have coverage biases and chimeric junctions occurring approximately every 20 kb. SAG-specific *de novo* genome assemblers, such as SPAdes are therefore recommended (Fig. 2), as they are optimized to correct for such data artifacts. Further, due to the amplification of low femtogram-range DNA via random hexamer primers, the single-cell genomics process is prone to contamination, and thus, thorough quality assessment and assurance (QA) of the data is advised (Bowers et al., 2017a). Several tools have been developed in recent years to facilitate single-cell data QA, such as ProDeGe (see "Relevant Websites section"), CheckM (see "Relevant Websites section"), acdc (see "Relevant Websites section"), and Anvio (see "Relevant Websites section").

Quality Considerations for Genomes From Uncultivated Microorganisms

MAGs and SAGs are often of draft quality, i.e., they are less complete and more fragmented than isolate genomes. The median completeness estimate of single-cell genomes from environmental cells is approximately 40%, though combined assembly of SAGs from the same species, as defined by average nucleotide identity (ANI), can yield more complete composite genomes. Only one complete, finished single-cell genome has been obtained to date. For MAGs, genomes are comparably incomplete, though several finished genomes have been reported (Albertsen et al., 2013; Brown et al., 2015). While most SAGs contain the SSU rRNA genes in the assembly, many MAGs do not due to the challenge of assembling and binning this highly conserved gene in a complex metagenome. When SSU rRNA genes are present, taxonomic inferences can be made based on the SSU rRNA gene based phylogeny, though phylogenetic placement of MAGs and SAGs is most often made through concatenated alignments of protein-coding single-copy marker genes.

Considering the variable quality of SAGs and MAGs, it is important to critically assess and report genomes quality. Recently, a set of community standards was put forward for reporting genome sequences of uncultivated microorganisms: the minimum information about a single amplified genome (MISAG) and a metagenome-assembled genome (MIMAG) of bacteria and archaea (Bowers et al., 2017b). MISAG and MIMAG encompass a minimal set of mandatory genome quality criteria, such as the reporting of genome completeness and contamination estimates. Considering the various different downstream analyses for SAGs and MAGs (e.g., basic metabolic reconstructions for comparative genomics, fragment recruitment for biogeographic analyses, and phylogenetic inference for evolutionary analysis and population genomics), reporting completeness and contamination estimates is imperative (Fig. 2), as some analyses require finished or high-quality genomes, while others may be feasible with medium- or low-quality genomes. Additionally, the consistent reporting of basic environmental metadata is suggested (Bowers et al., 2017b), as downstream comparative genomics is only as good as the metadata of a genomic dataset. Adhering to these standards will facilitate more reproducible and robust data interpretation and comparative genomic analysis to make solid inferences about evolutionary relationships and ecosystem functions of uncultivated bacteria and archaea.

From Individual Cells to Ecosystems

The tremendous diversity of microbes that impact the environment, animal and plant health, and serve as major drivers of global biogeochemical cycles have remained largely uncatalogued and underexplored. Major scientific advances within the past decade have been achieved through applying single-cell genomics and genome-resolved metagenomics. In particular, the microbial tree of life has greatly expanded with genomic information from newly identified candidate phyla (those phyla for which no cultivated isolate exists). The Patescibacteria were first described using single-cell genomics (Rinke et al., 2013) and later expanded through genome-resolved metagenomics to the Candidate Phyla Radiation (CPR) (Brown et al., 2015). This group of bacteria has small reduced genomes and lacks certain ribosomal proteins, implying divergent and unusual ribosome structures and biogenesis mechanisms (Brown et al., 2015). Complementary to the Patescibacteria, C. J. Castelle and colleagues utilized genome-resolved metagenomics to characterize deep-branching lineages constituting a large radiation within the Archaea with similarly small genomes that encode metabolic capacity for carbon and hydrogen metabolism relevant to Earth's biogeochemical cycles. Further, metagenomic reconstructions of candidate phyla from the Archaea provided unique insight into the origin and evolution of the eukaryotes through the recovery of the Asgard superphylum (Zaremba-Niedzwiedzka et al., 2017). While the exact phylogenomic placement of this clade is currently hotly debated, these genomes are enriched for proteins of eukaryotic origin, including homologues of eukaryotic membrane-trafficking machinery components and vesicle biogenesis.

Beyond cataloguing phylogenomic diversity, single-cell genomics and genome-resolved metagenomics have enabled important insights into how microbial metabolisms impact elemental fluxes and how those transformations influence ecosystem processes. For example, novel modes of metabolic coupling in the candidate phylum Marinimicrobia (formerly SAR406 and Marine Group A) were recently revealed by A. K. Hawley and colleagues through single-cell genomics with important implications for sulfur and nitrogen cycling. Similarly, single-cell genomic approaches utilized by D. Tsementzi and colleagues uncovered genes for respiratory nitrate reductases (Nar) encoded within certain clades of the highly abundant marine bacterium SAR11. Heterologous expression of the putative SAR11 *nar* operons verified functionality for the first step of denitrification, linking this important marine microbe to nitrogen loss pathways within oxygen minimum zones and expanding its known ecological niche. Furthermore, genome-resolved metagenomic approaches have led to major advances in understanding carbon fluxes mediated by uncultivated lineages, including methane metabolism in the archaeal phylum Bathyarchaeota and carbon fixation in the bacterial phyla *Candidatus* Eremiobacteraeota and *Candidatus* Dormibacteraeota (formerly WPS-2 and AD3, respectively). Importantly, functional capabilities can be tracked through better genomic representation of uncultivated lineages to shed light on key evolutionary origins. An elegant example by Soo et al. (2017) demonstrated independent acquisition of aerobic respiratory complexes within the three classes of Cyanobacteria (*Oxyphotobacteria*, *Melainabacteria*, and *Sericytochromatia*), supporting the hypothesis that aerobic respiration evolved after oxygenic photosynthesis approximately 2.3 billion years ago.

Owing to their synergy, single-cell genomics and genome-resolved metagenomic approaches are increasingly being used in combination (Fig. 3). Single-cell genomics offers genome-level resolution from an individual cell and can provide better spatial

Fig. 3 From cells to ecosystems. Single cells provide genome-level and spatial resolution, which are critical to understand population structure in heterogeneous communities. MAGs from bulk metagenomes are produced at much higher throughput and without the bias of cell isolation and whole genome amplification. Mini-MAGs can be generated by subsampling an environmental sample.

resolution. However, partial genome recovery and the need for specialized instrumentation and whole genome amplification results in low throughput and biases. On the other hand, genome-resolved metagenomics provides a “consensus” genome which is typically more complete compared to SAGs (provided sufficient sequencing and a high-quality metagenome assembly), incorporating genetic information from genotypically heterogeneous populations. It is currently challenging to resolve strain-level variation from MAGs, although new approaches have recently been developed to address these challenges. Early studies applying both technologies predominantly utilized the partial SAGs to recruit metagenomic data, but more recent studies leverage both approaches to examine species diversification, adaptive properties and ecological patterns within microbial communities. Further, aspects of both single-cell and shotgun metagenome strategies have been combined through a newly described microfluidics-based mini-metagenomic method from F. B. Yu and colleagues, which allows single-cell resolution and improved genome recovery. We anticipate future studies leveraging both single-cell genomics and metagenomics will make significant strides towards addressing fundamental questions in microbial ecology, niche partitioning and microbial evolution.

Fig. 4 Percentage of genes without a predicted function for bacterial and archaeal isolate genomes, SAGs and MAGs, illustrating a large knowledge gap in function assignment. Data were extracted from the Integrated Microbial Genomes and Microbiomes platform (<https://img.jgi.doe.gov>, IMG/M) on 1/16/2018.

Future Outlook

The tremendous increase in genomes from uncultivated microorganisms (Fig. 1), including from candidate phyla with no cultivated representatives, provides an exciting foundation for the functional interrogation of this microbial dark matter. The down side of the data deluge, however, is the increasing gap in our ability to assign function to many of the newly discovered genes, proteins, and pathways (Fig. 4). Steps to fill the function gap are most commonly achieved by moving from sequence to function via designing experiments to validate sequence-based predictions of function; these experiments rely on technologies such as DNA synthesis and protein expression followed by a functional assay. An alternate approach is “function-driven” (meta)genomics. Here moving from function to sequence, prior to sequencing, cells or DNA from organisms are selected and enriched based on a particular phenotype. Function-driven single-cell genomics (Doud and Woyke, 2017) may target cells of general metabolic activity or highly specific activities, as demonstrated in a recent study by M. Martinez-Garcia and colleagues, where populations degrading the substrate laminarin were captured and genome sequenced following the addition of a fluorescently labeled form of laminarin. Analogous to these approaches is the application of stable isotope probing (SIP) to link microbial activity (function) to taxonomic identity within an environmental sample. This function-driven metagenomic approach relies on the incorporation of heavy isotopes (for example, ^{13}C) into microbial DNA during growth on labeled substrates. Early successes of the technology include the identification of dimethyl sulphide (DMS) functional capacity within previously unknown bacterial groups by O. Eysce and colleagues, and most recently, the application of DNA-SIP for genome-resolved metagenomics by R. M. Ziels and colleagues. While a very promising approach, DNA-SIP is currently not widely utilized because it requires specialized laboratory equipment and technical expertise. However, we anticipate with advanced high-throughput protocols relying on robotic automation, along with improvements in depth of coverage for low-biomass samples, this technology will become more broadly accessible. While there is no magic bullet for validating function, and the aforementioned approaches are often rather custom, tedious and low throughput, it is important to continue making progress on the functional verification of genome sequence space. The integration of functional and phenotypic data with genomics will ultimately move us towards a better systems biology and ecosystem understanding of uncultivated bacterial and archaeal taxa.

ORF	Open reading frame

Defining Statement

This article reviews the evidence indicating the energy-storage role of glycogen. Nutritional and physiological conditions enabling microorganisms to accumulate the polysaccharide as well as the reactions involved in their biosynthesis and subsequent utilization are described. In addition, the current state of knowledge of regulation of glycogen synthesis is discussed.

Introduction

Many bacteria accumulate glycogen, a polysaccharide that is considered to function as an energy reserve. Glycogen may accumulate during growth or at the end of the growth phase and may act as a source of energy no longer available from the environment. Glycogen usually accumulates when there is a carbon excess in the medium; that is, growth is limited by a nutrient other than the carbon source. The concentration of accumulated glycogen is dependent on the nutrient content of the medium as well as the growth phase of the organism and can at times be very high, at least 50% of the cell's dry weight. An advantage in using glycogen as a reserve storage compound is that because of its high molecular weight and physical properties, it has little effect on the internal osmotic pressure in the cell.

Various aspects of the enzymology and regulation of bacterial glycogen synthesis, including genetic regulation, have been extensively reviewed in the literature.

Criteria for Designating an Energy-Storage Function to a Compound

J.F. Wilkinson (1959) proposed three criteria for classification of compounds having energy-storage function. First, the compound should accumulate intracellularly under conditions in which the energy supply for growth of the organism is in excess. Second, the reserve polymer should be used when the components of energy or carbon in the media are no longer available for sustaining growth or other processes required for maintenance of viability. Wilkinson pointed out various cell functions that would require energy or carbon, for example, maintenance of a functioning semipermeable cytoplasmic membrane, replacement of proteins and nucleic acids during turnover, maintenance of intracellular pH, or other processes induced for bacterial survival, such as sporulation and encystment.

Third, the storage compound should be used by the cell for energy production that would enable it to survive in a nonsupportive environment. This energy required for survival is known as 'energy of maintenance'. This last criterion is perhaps the most important, for as Wilkinson notes, a number of other substances may be produced for other functions, such as, 'To detoxicate end products of metabolism which otherwise accumulate too rapidly and prove toxic.'

[☆]*Change History:* October 2014. J. Preiss introduced small edits in the text of the article. No edits in figures except figures 3 and 4 have been reversed in the order. Added new references to 'Further Reading' section.

This article is an update of J. Preiss, Glycogen Biosynthesis, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 145–158.

Occurrence of Glycogen in Bacteria

Many bacterial species accumulate glycogen either in stationary phase or under limited growth conditions with excess carbon in the medium. For *Escherichia coli* the rate of growth and the quantity of accumulated glycogen were inversely related when the cells were grown in media containing glucose as the carbon source and limited in nitrogen. Some bacteria, however, can optimally synthesize glycogen during exponential growth. Glycogen does not seem to be required for growth, since bacterial mutants having defective structural genes for the glycogen biosynthetic enzymes, and thereby unable to synthesize glycogen, can grow as well as their normal parent strains.

Glycogen or other similar α -1,4 glucans have been reported in more than 50 different bacterial species. The polysaccharide is not restricted to any class of bacteria as many Gram-negative and Gram-positive bacteria as well as archaeobacteria have been reported to accumulate glycogen.

In many studies, it has been shown that glycogen accumulates in stationary phase, when growth either ceases because of the depletion of a nutrient, for example, nitrogen in the form of ammonia or amino acid, or diminishes because of unfavorable pH. When studied in detail, it is usually found that the largest accumulation of glycogen occurs under nitrogen-limited conditions.

Biological Functions of Bacterial Glycogen

Various strains of *E. coli*, *Enterobacter aerogenes*, and *Streptococcus mitis* not containing glycogen have been compared with strains containing glycogen, with respect to their viability in media having no exogenous carbon source. A more prolonged survival rate was observed for the strains containing glycogen. Moreover, it was shown that under starvation conditions, the glycogenless enteric cells degraded their RNA and protein constituents to NH_3 . This either did not occur or occurred at a lower rate in cells containing glycogen. It was postulated that when glycogen was available, its use as an energy source minimized RNA and protein degradation for production of energy.

In various *Clostridium*, *Bacillus* and *Streptomyces viridochromogenes*, a glycogen-like molecule is accumulated up to 60% of the cell's dry weight before the onset of sporulation. The polysaccharide is then degraded during formation and maturation of the spore. Hence, it is believed that glycogen serves as an endogenous source of carbon and energy for spore formation. Although many experiments suggest that glycogen plays a role in the survival of bacteria, its precise function remains unclear. Further clarification on the role of bacterial glycogen is needed.

The synthesis and later degradation of glycogen by some oral bacteria may be an important factor in the development of dental caries. Consistent with this postulate are the findings that these organisms are capable of synthesizing glycogen, produce more acid when exogenous carbohydrate is present, and can produce acid in the absence of exogenous carbohydrate, when compared with oral bacteria that are unable to synthesize glycogen. The acid formed from polysaccharide catabolism may be of significance in the development of dental caries. It is formed over a considerable period of time and may consequently be responsible for the lower resting pH observed in dental plaque sampled from individuals with active caries.

Structural Studies of Glycogen

Microbial glycogen is very similar to mammalian glycogen in that it is composed mainly of α -1,4-glucosyl linkages and is a branched polysaccharide with about 8–12% of the glucosyl linkages being α -1,6.

Most bacterial glycogen structurally studied have chain lengths of ~ 10 – 13 glucose units and I_2 spectra with maximum absorption of ~ 410 – 480 nm. However, the bacterial α -glucans can differ to some extent in their structural properties, and the variation is attributable to a number of factors, including the relative amounts and types of branching and debranching activities.

Enzymatic Reactions Involved in Glycogen Synthesis

Sugar Nucleotide Pathway

Elaine Greenberg and Jack Preiss showed in 1964 that extracts of several bacteria contained both an ADP-Glc PPase synthetase (eqn [1]) and an ADP-Glc-specific glycogen synthase (eqn [2]):

Subsequently, it was shown that branching enzyme activity (eqn [3]) was also present in many bacterial extracts and photo-synthetic organisms.

Synthesis of Glycogen Directly from Disaccharides

α -Glucans similar to glycogen have been shown to be formed from either sucrose or maltose. When *Neisseria* strains are grown on sucrose, they accumulate large amounts of a glycogen-type polysaccharide. The direct conversion of sucrose to an α -1,4 glucan (eqn [4]) is catalyzed by the enzyme amylosucrase. The glucosyl moiety of sucrose is transferred to a primer to form a new α -1,4-glucosidic linkage. The gene for the *Neisseria polysaccharea* amylosucrase has been cloned and can be expressed in *E. coli in vitro*; the product formed is unbranched. Thus in *Neisseria* strains the α -1,6 linkages formed must be due to a branching enzyme activity:

Amylosucrase is limited to a few bacterial strains and is only induced in the presence of sucrose. Moreover, there are no reports that indicate that either *Neisseria* or any other bacteria are able to synthesize sucrose from other metabolites. Thus, accumulation of glycogen in *Neisseria* and in other bacteria grown on other carbon sources besides sucrose cannot be mediated by amylosucrase action.

A number of enteric and other organisms when grown on maltose or maltodextrins as a carbon source can synthesize a low-molecular-weight α -1,4-glucan via transfer of the glucosyl moiety of maltose to a growing α -1,4-glucan chain (eqn [5]). The enzyme catalyzing this reaction is amylomaltase:

The polymer is of very low molecular weight and is quickly degraded by another enzyme, maltodextrin phosphorylase, which is also induced by the presence of maltose in the medium. The synthesis of these two enzymes, however, is repressed by glucose, and thus neither amylomaltase nor maltodextrin phosphorylase activity would be responsible for synthesis of glycogen when the organisms are grown on carbon sources other than maltose.

Glycogen phosphorylase, as well as maltodextrin phosphorylase, is found in many bacteria and can catalyze synthesis or phosphorolysis of α -1,4-glucosyl linkages either in maltodextrins or in glycogen:

However, maltodextrin phosphorylase is usually induced only in the presence of maltose or maltodextrins. *E. coli* mutants deficient in this enzyme accumulate maltodextrins, indicating that maltodextrin phosphorylase is involved in degradation of the α -glucans rather than in synthesis. The glycogen phosphorylase activity found in organisms is usually insufficient to account for the rate of synthesis observed.

In summary, it appears that glycogen synthesis in bacteria occurs mainly by the sugar nucleotide pathway. Both *E. coli* and *Salmonella typhimurium* mutants, either glycogen deficient or containing glycogen in excess of that observed in the parent wild-type strain, have been isolated. They are affected either in their glycogen synthase or in their ADP-Glc synthetase activity, implying that in these organisms, the ADP-Glc pathway is the major, if not exclusive, route for glycogen formation.

Properties of the Glycogen Biosynthetic Enzymes

ADP-glucose Pyrophosphorylase

ADP-Glc PPase has been purified from a number of microorganisms, and, with one exception, the enzyme has been found to be homotetrameric in structure with a subunit molecular size of about 50 kDa. The one exception enzyme, in *Bacillus stearothermophilus*, is also a tetramer, but is composed of two subunits: GlgC, of 387 amino acids with a molecular size of 43.3 kDa, and GlgD, of 343 amino acids with a molecular size of 39 kDa. The *Bacillus* enzyme is thus similar to the higher plant ADP-Glc PPases, which also have been shown to be heterotetrameric, $\alpha_2\beta_2$. In the plant enzyme, the small subunit is also known as the catalytic subunit, and the large subunit is known as the regulatory subunit. The potato tuber ADP-Glc PPase catalytic subunit expressed alone in *E. coli* is highly active while the large subunit by itself is inactive. Expression of both the subunits of potato tuber ADP-Glc PPase together results in a heterotetramer having higher affinity for the allosteric activator and lower affinity for the inhibitor. Therefore the large subunit is regarded as the regulatory subunit. The *B. stearothermophilus* GlgC subunit shows a 42–70% similarity in amino acid sequence with other ADP-Glc PPases and when expressed alone in *E. coli* shows catalytic activity. The *Bacillus* GlgD subunit shows no activity, and its function is unknown. However, it seems to increase the $V_{\max}$ of the GlgC activity, and slightly increases the apparent affinity of GlgC for the substrates.

An important facet of both bacterial and plant ADP-Glc PPases is that they are allosteric enzymes, and the allosteric function is important for the regulation of bacterial glycogen and plant starch synthesis rates. More than 50 ADP-Glc PPases – mainly bacterial, but also plant – have been studied with respect to their regulatory properties. In almost all cases, glycolytic intermediates activated ADP-Glc synthesis while AMP, ADP, or P_i were inhibitors. Glycolytic intermediates in the cell can be considered as indicators of carbon excess and, therefore, under conditions of limited growth with excess carbon in the media, accumulation of glycolytic intermediates would be signals for the activation of ADP-Glc synthesis. For most of the ADP-Glc PPases studied, the activator

glycolytic intermediate increases the enzyme's apparent affinity for the substrates, ATP and glucose-1-P, and increasing concentrations of activator reverse the inhibition caused by the inhibitors, AMP, ADP, or P_i .

The activator specificity of the bacterial and plant ADP-Glc PPases can be categorized into seven groups (Table 1) on the basis of their specificity of activation by the various glycolytic intermediates. The variation of activator specificity observed correlates with the nature of carbon assimilation dominant in the bacterium or plant tissue. *E. coli* or *S. typhimurium* obtain their energy mainly through glycolysis. The primary activator for their ADP-Glc PPases is fructose 1,6-bisP, 5''-adenylate is the major inhibitor, and their ADP-Glc synthetic activity is regulated by the [fructose 1,6-bisP]/[AMP] ratio. In plants and in the cyanobacteria, the activator is 3-P-glycerate (3PGA) and the inhibitor is P_i . 3PGA is the primary product in the carbon assimilation pathways of these photosynthetic organisms/tissues.

In plants there can be different patterns of interaction between the activator 3PGA and inhibitor P_i . For most plants the interaction is simply increasing 3PGA concentrations reversing P_i inhibition or increasing P_i concentrations reversing 3PGA activation. However 3PGA is not an activator of wheat endosperm ADP-Glc PPase, but can reverse P_i inhibition. The maize endosperm ADP-Glc PPase as well as some CAM ADP-Glc PPases is not inhibited by P_i but does reverse or inhibit 3PGA activation. Barley endosperm is neither inhibited by P_i , nor activated by 3PGA. However they do affect the barley enzyme activity by 3PGA increasing the affinity for the substrate, ATP, and P_i reversing the 3PGA effect.

Evidence has accumulated to indicate, that the *in vitro* observed kinetic allosteric activation and the inhibitor effects occur *in vivo* in bacterial cells. There is a class of mutants of *E. coli* and of *S. typhimurium* LT2 affected in their ability to accumulate glycogen. This mutant class has ADP-Glc PPases with altered regulatory properties. Generally, the mutants with ADP-Glc PPases having higher affinity for the activator, fructose 1,6-bisphosphate, and/or a lower affinity for the allosteric inhibitor, AMP, accumulate glycogen at a faster rate than their parent wild-type strains; mutants with enzymes having a lower affinity for the activator accumulate glycogen at a lower rate than does the parent strain.

Table 2 summarizes the allosteric properties of the mutant ADP-Glc PPases that have been studied and their ability to accumulate glycogen in the stationary phase. With respect to *E. coli*, there is a direct relationship between the affinity of the enzyme for the activator and the ability of the mutant to accumulate glycogen. If the apparent affinity for the activator, fructose-1,6-bisP, is higher, glycogen accumulation by the mutant is higher. If the apparent affinity for activator is lower, as seen for mutant SG14 enzyme, glycogen accumulation is lower in the mutant than in the parent strain. The two *S. typhimurium* mutant strains have ADP-Glc PPases that are more affected in their affinity for the inhibitor. Both JP23 and JP51 enzymes have lower affinity for the inhibitor,

Table 1 ADPglucose pyrophosphorylases classified with respect to activator specificity for the specific organisms that have been studied

Activator(s)	Microorganisms	Predominant carbon assimilation pathway
Pyruvate	<i>Rhodospirillum</i> sp. <i>Rhodocyclus purpureus</i>	Reductive pyruvate cycle
3-P-Glycerate	Cyanobacteria (higher plants)	Photosynthetic calvin cycle

The amino acids identified by chemical modification and site directed mutagenesis to be involved in binding are in bold and underlined.

and these mutants accumulate higher amounts of glycogen than does the parent strain. Of interest is that JP23 ADP-Glc PPase is fully active in the absence of activator. Addition of activator fructose-1,6 bisP causes no further increase in activity.

The above studies plus the one showing a direct relationship between the fructose 1,6-bisP concentration in the *E. coli* cell and the rate of glycogen accumulation clearly point out that fructose 1,6-bisP is an allosteric activator of ADP glucose pyrophosphorylase and a physiological activator of glycogen synthesis in *E. coli* and in *S. typhimurium*.

Chemical modification and site-directed mutagenesis studies of the ADP-Glc PPases have provided evidence of the location of the activator binding site, the inhibitor binding site, and the substrate binding sites. These experiments have used pyridoxal-P as an analogue either for the activator, fructose 1,6-bisP, or, as subsequently shown, for the substrate, glucose-1-P. For an ATP analogue, the photoaffinity reagent 8-azido-ATP (8N₃ATP) proved to be a substrate for the *E. coli* enzyme, whereas 8-azido AMP (8N₃AMP) was an effective inhibitor analogue. Since the *E. coli* ADP-Glc PPase gene, *glgC*, had been cloned and its sequence determined, the identification of the amino acid sequence of the modified residue enabled one to determine the location of the modified residue in the primary structure of the enzyme. The amino acid residue involved in binding the activator was Lys39 and the amino acid involved in binding the adenine portion of the substrates (ADP-Glc and ATP) was Tyr114. Tyr114 was also the major binding site for the adenine ring of the inhibitor, AMP. Lys195 is protected from reductive phosphopyridoxylation by the substrate, ADP-Glc. It was proposed that Lys195 is also a part of the substrate binding site. Moreover, Asp142 has been shown to be the catalytic residue of the *E. coli* ADP-Glc PPase.

Similar experiments were also conducted to elucidate the activator, 3PGA, inhibitor, P_i, and substrate, Glc-1-P sites in *Anabaena* PC7120 and in the potato tuber and spinach leaf ADP-Glc PPases. Table 3 shows the amino acid sequences of the substrate and allosteric sites identified via chemical modification in the bacteria, *E. coli* and *Anabaena*, as well as in the higher plant enzymes. The sequence for the Glc-1-P substrate site is highly conserved for both bacterial and higher plant ADP-Glc PPases.

The ADP-Glc PPase of *Agrobacterium tumefaciens* has been cloned and expressed in *E. coli*. This enzyme has as activators, fructose-6-P and pyruvate, and an activator specificity different from that of the *E. coli* ADP-Glc PPase. Mutagenesis of the homologous Arg25 in the enzyme from *A. tumefaciens* yields an enzyme with an activity reduced by two orders of magnitude. Generally, it is expected that more dramatic effects would result from mutation of catalytic residues. Most probably in *A. tumefaciens* ADP-Glc PPase the catalytic residue equivalent to the *E. coli* enzyme Asp142 is Asp135.

Cloning of ADP-Glc PPases with Altered Allosteric Properties from *E. Coli* Mutants Affected in Glycogen Synthesis

As indicated above (Table 2), a class of mutants of *E. coli* and of *S. typhimurium* with altered rates of glycogen accumulation was found to have ADP-Glc PPases that were affected in their allosteric properties. To gain insight with respect to amino acid residues or domains involved in maintaining allosteric function the allosteric mutant ADP-Glc PPases were cloned.

Table 2 shows the various amino acid substitutions in the allosteric mutants that have been cloned and analyzed. Of interest is that the mutations causing large changes in the allosteric properties of the enzyme occur throughout the sequence of the ADP-Glc PPase. These changes of amino acids in the enzyme affect not only the affinity of the allosteric effectors (Table 2), but also the apparent affinities for the substrates ATP and Mg²⁺. Thus, there are many domains affected by the mutations.

Site-directed mutagenesis of the ADP-Glc PPase gene and analysis of various allosteric mutant genes have provided much information in the structure-function relationships of the substrate and catalytic sites. What is needed for greater clarification is knowledge on the three-dimensional structure of the enzyme. Information on the three-dimensional structure of an ADP-Glc PPase is currently available for the plant enzyme, potato tuber ADP-Glc PPase, but not for the bacterial ADP-Glc PPase. However, several methods have been utilized to predict the ADP-Glc PPase enzyme structure. A 'hydrophobic cluster analysis' (HCA) was applied to several ADP-Glc PPases from different sources representing different classes, for example, *E. coli*, *Anabaena*, *Chlamydomonas*, potato

(*Solanum tuberosum* L.) tuber 'small' subunit, and different 'large' subunits from maize embryo, maize shrunken 2 and *Arabidopsis thaliana*. The cluster analysis strongly indicated that ADP-Glc PPases are extremely similar in the distribution and pattern of the clusters, in both bacterial and plant enzymes. Thus it is certainly possible that the ADP-Glc PPases share a common folding pattern, even though there is a different quaternary structure as seen for $\alpha_2\beta_2$ in plants and α_4 in bacteria.

A model has been proposed in which the conserved amino acids known to have specific roles in the binding of substrates (Tyr114, Lys195 in *E. coli*) and activators (Lys39 in *E. coli*, Lys382, Lys419 in *Anabaena*) are located in loops. The residues Pro295 and Gly336 seem to be located in a region important for the regulation of the *E. coli* enzyme and are also in loops. The amino acid residue Asp142 in the *E. coli* enzyme was identified as a catalytic residue and is also situated in a loop.

A structure that is observed in proteins that bind nucleotides is also predicted in this model. Region 1 of the ADP-Glc PPase has a Gly-rich loop after a β -sheet, which is similar to a 'P loop' in protein kinases or nucleotide binding sites, and region 2 has three β -sheets and helices that are compatible with the Rossmann fold. Thus, regions 1 and 2 comprise a putative domain or subdomain that binds ATP. Moreover, Tyr114, which was shown to be reactive with the azido analogue of ATP, is present in this region.

The first pyrophosphorylase domain crystallized and solved was present in a bifunctional enzyme that is the expression product of the gene *glmU*. One domain of the GlmU protein is a UDP-N-acetylglucosamine pyrophosphorylase, and the other is an acetyltransferase. Later, other pyrophosphorylase domain structures were solved. All these studies verify the predicted secondary-structure model of the ADP-Glc PPase. The idea that the sugar-nucleotide pyrophosphorylases share a similar catalytic domain is supported by the observation that the homologous Glc1-P site is present in the GDPMan PPase from *Pseudomonas aeruginosa*.

Glycogen Synthase

The bacterial glycogen synthases are specific for the sugar nucleotide ADP-Glc. In cases where it has been studied, the enzyme subunit size is about 50 kDa, and the enzyme in its native form is either a dimer or homotetramer.

An affinity analogue of ADP-Glc, adenosine diphosphopyridoxal (ADP-pyridoxal), was used to identify the ADP-Glc-binding site. Incubation of the enzyme with the analogue plus sodium borohydride led to an inactivated enzyme. The degree of inactivation correlated with the incorporation; about 1 mol of analogue per mole of enzyme subunit resulted in 100% inactivation. After tryptic hydrolysis, one labeled peptide was isolated, and the modified Lys residue was identified as Lys15. The sequence, Lys-X-Gly-Gly, where lysine is the amino acid modified by ADP-pyridoxal, has been found to be conserved in the mammalian glycogen synthase and the plant starch synthases.

The structural gene for glycogen synthase, *glgA*, has been cloned from *E. coli*, *S. typhimurium*, *A. tumefaciens*, and *B. stearothermophilus*, and the nucleotide sequences of these organisms have been determined. The *E. coli* glycogen synthase sequence consists of 1431 bp specifying a protein of 477 amino acids with a molecular weight of 52412 Da. Its availability has enabled researchers to perform site-directed mutagenesis experiments to determine structure-function relationships for a number of amino acids in the *E. coli* glycogen synthase. Substitution of other amino acids for Lys at residue 15 suggested that the Lys residue is mainly involved in binding the phosphate residue adjacent to the glycosidic linkage of the ADP-Glc and not in catalysis. The major effect on the kinetics of the mutants at residue 15 was the elevation of the K_m of ADP-Glc, of about 30- to 50-fold, when either Gln or Glu was the substituted amino acid. Substitution of Ala for Gly at residue 17 decreased the catalytic rate constant, k_{cat} , about three orders of magnitude compared with the wild-type enzyme. Substitution of Ala for Gly 18 only decreased the rate constant 3.2-fold. The effect on the K_m of the substrates, glycogen and ADP-Glc, was minimal. It was postulated by the researchers that the two glycyl residues in the conserved LysX-Gly-Gly sequence participated in the catalysis by assisting in maintaining the correct conformational change of the active site or by stabilizing the transition state.

Since there still existed binding of the ADP-Glc and appreciable catalytic activity of the Lys15Gln mutant, the ADP-pyridoxal modification was repeated and in this instance about 30 times higher concentration was needed for inactivation of the enzyme. The enzyme was maximally inhibited about 80%, and tryptic analysis of the modified enzyme yielded one peptide containing the affinity analogue and with the sequence Ala-Glu-Asn-modified Lys-Arg. The modified Lys was identified as Lys277. Site-directed mutagenesis of Lys277 to form a Gln mutant was carried out, and the K_m for ADP-Glc remained essentially unchanged but k_{cat} decreased 140-fold. It was concluded that Lys277 was more involved in the catalytic reaction than in substrate binding.

A cysteine-specific reagent 5,5'-dithiobis(2-nitrobenzoic acid) was shown to inactivate the *E. coli* glycogen synthase. To determine the responsible residue, all cysteine residues present in the enzyme, Cys7, Cys379, and Cys408, were substituted with Ser. 5,5'-Dithiobis(2-nitrobenzoic acid) modified and inactivated the enzyme only if Cys379 was present. The inactivation was prevented by the substrate ADP-Glc. Mutations C379S and C379A increased the $S_{0.5}$ for ADP-Glc 40- and 77-fold, whereas the enzyme-specific activity was decreased 5.8- and 4.3-fold, respectively. Studies of inhibition by glucose 1-phosphate and AMP indicated that Cys379 was involved in the interaction of the enzyme with the phosphoglucose moiety of ADP-Glc. Other mutations, C379T, C379D, and C379L, indicated that this site is intolerant for larger side-chains. Because Cys379 is in a conserved region, other residues were scanned by mutagenesis. Replacement of Glu377 by Ala and Gln decreased V_{max} more than 10 000-fold without affecting the apparent affinity for ADP-Glc and glycogen binding. Mutation of Glu377 by Asp decreased V_{max} only 57-fold, indicating that the negative charge of Glu377 is essential for catalysis. The activity of the mutation E377C, on an enzyme form without other Cys, was chemically restored by carboxymethylation. Other conserved residues in the region, Ser374 and Gln383, were analyzed by mutagenesis but were found not to be essential. Comparison with the crystal structure of other glycosyltransferases suggests that this conserved region is a loop that is part of the active site. Thus, the results of this study indicate that this region is critical for catalysis and substrate binding, with Glu377 being the catalytic residue.

Figure 1 Schematic representation of the putative binding site of ADP-glucose in the glycogen synthase. The residues that are observed interacting with the ADP-Glc structure are in blue and red color. The ADP-Glc structure is in green.

Glycogen synthases are glucosyl transferases that retain the anomeric configuration of glucosyl linkage of ADP-Glc to the nonreducing end of glycogen. The *E. coli* glycogen synthase was therefore modeled based on three other glycosyl linkages retaining glycosyltransferases having a GT-B fold. Comparison between this model and the structure of the active sites of crystallized glycosyl linkages retaining GT-B glycosyltransferases identified conserved residues in glycogen synthase with the same topology. These residues were studied in the *E. coli* glycogen synthase by site-directed mutagenesis to confirm their importance predicted by the model. Mutations D137A, R300A, K305A, and H161A decreased the specific activity 8100-, 2600-, 1200-, and 710-fold, respectively. None of these mutations increased the K_m for glycogen, and only H161A and R300A had a higher K_m for ADP-Glc of 11- and 8-fold, respectively. These residues were essential, validating the model that shows a strong similarity between the active site of *E. coli* glycogen synthase and the others retaining GT-B glycosyltransferases, known to date.

The alignment of the amino acid residues essential for catalysis in the enzymes retaining glycosyltransferases – trehalose-P synthase, maltose phosphorylase, and a muramoyl *N*-acetylglucosaminyl transferase, AceA – in the glycogen synthase has been proposed. Recently, the glycogen synthase crystal structure has been elucidated and confirms the correctness of the proposed model. Figure 1 shows a schematic representation of the putative binding site for ADP-Glc in the glycogen synthase.

Branching Enzyme

The structural genes of various branching enzymes (BE) have been cloned from many bacteria. The nucleotide and deduced amino acid sequences of the *E. coli* *glgB* gene consisted of 2181 bp specifying a protein of 727 amino acids and with a molecular weight of 84 231 Da.

The amino acid sequences of BEs and amylolytic enzymes such as α -amylase, pullulanase, glucosyltransferase, and cyclodextrin glucanotransferase have been compared, and there is a marked conservation of the amino acid sequence of the four catalytic regions of amylolytic enzymes in the BEs irrespective of whether they are of bacterial, plant, or mammalian origin. As shown in Table 4 four

Table 4 Comparison of primary structures of various branching enzymes with the four best-conserved regions of the α -amylase family

Enzyme	Region 1	Region 2	Region 3	Region 4
<i>B. subtilis</i> α -amylase	100DAVINH	171GFRFDAAKH	204FQYGEILQ	262VTWVESHD
Maize endosperm BE I	277DVVHSH	347GFRFDGVTS	402TVVAEDVS	471IAYAESHD
Potato tuber BE	355DVVHSH	424GFRFDGITS	453VTMAEEST	547VTYAESHD
Rice seed BE 1	271DVVHSH	341GFRFDGVTS	396TIVAEDVS	462VTYAESHD
<i>E. coli</i> glycogen BE	335DWVPGH	400ALRVDAVAS	453VTMAEEST	518VFLPLNHD

The sequences have been derived from references cited in the text. Just α -amylase of the enzymes from the α -amylase family are compared with *E. coli* glycogen BE. However, Svensson and her colleagues show comparisons of over 40 enzymes ranging from amylases, glucosidases, various α -1,6-debranching enzymes as well as 4 cases of branching enzymes. The invariant amino acid residues are in bold letters

regions that putatively constitute the catalytic regions of the amylolytic enzymes are conserved in the plant branching isoenzymes and the glycogen BEs of *E. coli*. Analysis of this high conservation in the α -amylase family has been pointed out and greatly expanded by B. Svensson and H.M. Jespersen and colleagues with respect to sequence homology and also in the prediction of (β/α)8-barrel structural domains with a highly symmetrical fold of eight inner, parallel β strands, surrounded by eight helices, in the various groups of enzymes in the family. The (β/α)8-barrel structural domain was determined from the crystal structure of some α -amylases and cyclodextrin glucanotransferases.

The conservation of the putative catalytic sites of the α -amylase family in the glycogen and starch BEs would be expected as the BE catalyzes two consecutive reactions in synthesizing α -1,6-glucosidic linkages by cleavage of an α -1,4-glucosidic linkage in a 1,4- α -D-glucan to form a non-reducing-end oligosaccharide chain that is transferred to a C-6 hydroxyl group of the same or another 1,4- α -D-glucan. The eight highly conserved amino acid residues of the α -amylase family are also functional in BE catalysis. The regions of the C- and N-terminus are dissimilar in sequence and in size in the various branching isoenzymes. Recent studies suggest that these amino acid sequence regions are important with respect to BE specificity and with respect to substrate specificity (amylose or amylopectin) as well as in the size of chain transferred and the extent of branching. Furthermore, truncation of 113 amino acids of the N-terminal of the *E. coli* BE, causes it to branch longer branch-chains than do the wild-type enzyme, further indicating that the N-terminal region is involved in determining the size of chain transferred. Recently, the crystal structure of a truncated form of the *E. coli* BE has been elucidated.

Genetic Regulation of Glycogen Synthesis in *E. coli*

As indicated before, the glycogen biosynthetic enzymes are induced in the stationary phase. The rate of glycogen synthesis is inversely related to growth rate when growth is limited for certain nutrients, for example, nitrogen. Consistent with this are the findings that the levels of glycogen biosynthetic enzymes in *E. coli* increase as cultures enter the stationary phase.

When *E. coli* or *S. typhimurium* cells are grown in an enriched medium and 1% glucose, the specific activities of ADP-Glc PPase and glycogen synthase increase 11- to 12-fold, while glycogen BE increases 5-fold, as cultures enter stationary phase. However, when the organisms are grown in a defined medium, the ADP-Glc PPase and glycogen synthase activities are relatively high in the exponential phase. BE in defined media is fully induced in the exponential phase, with only about a twofold increase in specific activity of the ADP-Glc PPase and glycogen synthase occurring when the cells reach the stationary phase. These experiments suggest that the gene encoding the BE is regulated differently from the genes for ADP-Glc PPase and glycogen synthase. The addition of inhibitors of RNA or protein synthesis to prestationary phase cultures prevents the enhancement of glycogen synthesis in the stationary phase, and this is expected for a pathway that is under transcriptional control.

Location of the Structural Genes for Glycogen Biosynthesis

The structural genes for glycogen biosynthesis are clustered in two adjacent operons, which also contain genes for glycogen catabolism. The structural genes for glycogen synthesis were shown to be located at approximately 75 min on the *E. coli* K-12 chromosome, and the gene order at this location was shown to be *glgA-glgC-glgB-asd*. These genes encode the enzymes glycogen synthase, ADP-Glc PPase, glycogen BE, and are close to *asd*, the structural gene for the enzyme aspartate semialdehyde dehydrogenase (EC 1.2.1.11).

The *E. coli* *glg* structural genes were cloned into pBR322 via selection with the closely linked essential gene *asd*. Among several *asd* + plasmid clones isolated, pOP12 was found to contain a 10.5-kb *Pst*I fragment which encoded the structural genes *glgC*, *glgA*, and *glgB*. The arrangement of genes encoded by pOP12 has also been determined by deletion mapping experiments, and the nucleotide sequence of the entire *glg* gene cluster has been resolved. The genetic and physical map of the *E. coli* K-12 *glg* gene cluster is shown in Figure 2. The continuous nucleotide sequence of over 15 kb of this genome region includes the sequences of the flanking genes *asd* and *glpD* (glycerol phosphate dehydrogenase; EC 1.1.99.5; 1.1.1.8).

Nucleotide sequence analysis indicated that in addition to the *glgC*, *glgA*, and *glgB* genes, pOP12 contains *glgX*, located between *glgB* and *glgC*, and *glgP*, located downstream from *glgA*. The gene *glgX* has recently been shown to express isoamylase activity.

The *glgP* gene is identified by homology with rabbit muscle glycogen phosphorylase. This gene encodes glycogen phosphorylase as shown via the expression and characterization of its gene product. Neither *glgX* nor *glgP* is needed for glycogen synthesis, suggesting that both may be more involved in glycogen catabolism.

Figure 2 Structure of the glycogen cluster in *Escherichia coli*. The restriction map is constructed from known contiguous sequences. All of these genes are transcribed from left to right (counterclockwise on the genome), except *glpD*.

The organization of the gene cluster suggests that the *glg* genes may be transcribed as two tandemly arranged operons, *glgBX* and *glgCAP* (Figure 2). The coding regions of *glgB* and *glgX* overlap by one base pair, *glgC* and *glgA* are separated by two base pairs, and genes *glgA* and *glgP* are separated by 18 base pairs. The close proximity of these genes suggests translational coupling within the two proposed operons. Studies of the regulation of the *glg* structural genes, with *lacZ* translational fusions and other approaches are consistent with a two-operon arrangement for the *glg* gene cluster, in which the *glgCAP* and *glgBX* operons may be preceded by phase-regulated growth promoters. Transcriptions initiating upstream of *glgC* have been analyzed by S1 nuclease mapping.

Genetic Loci Affecting Glycogen Biosynthetic Enzyme Levels in *E. coli*

Studies of glycogen-excess *E. coli* B mutants SG3 and AC70R1, which exhibit enhanced levels of the enzymes in the glycogen synthesis pathway, suggested that glycogen synthesis is under negative genetic regulation. The mutations in these strains *glgR* and *glgQ* affect *glgA* and *glgC* transcription respectively, although these mutations have not been isolated and sequenced.

Four 5' termini *in vivo* transcripts were identified within 0.5 kb of the upstream region of the *glgC* coding region by S1-nuclease protection analysis (Figures 2 and 3). Three of these transcripts were mapped to high resolution and their sequences are as shown in Figure 3.

The *glgR* mutation is closely linked to the glycogen structural genes by P1 transduction analysis, and the mutation results in 8- to 10-fold higher levels of ADP-Glc PPase and 3- to 4-fold higher levels of glycogen synthase in exponential phase, but does not alter the level of BE in minimal media. Analysis of RNA transcripts for *glgC* in strain SG3 having the *glgR* mutation reveals an increase in transcript B only (Figures 2 and 3). Therefore, it appears that the *glgR* mutation may alter a *cis*-acting site involved in the regulation of transcript B. This effect might be mediated via a negative regulatory site, but the current experimental evidence also is consistent with an overexpressed phenotype or a higher affinity CRP-binding site.

The *glgQ* mutation is not linked to the glycogen gene cluster in P1 transduction, and results in 11-, 5.5-, and 2-fold increases in ADP-Glc PPase, glycogen synthase, and glycogen BE, respectively. Therefore, *glgQ* appears to affect one or more *trans*-acting factors for the expression of the genes in the two glycogen operons. Levels of the four transcripts for the *glgC* gene are elevated in the *glgQ* mutant, AC70R1 (Figures 2 and 3). Transcript A was affected the most dramatically, with approximately 25-fold higher levels being present in AC70R1 versus the wild-type *E. coli* B or the SG3 strain. Since the levels of BE are also elevated in AC70R1, it was not considered likely that *glgQ* was a mutation in the cAMP-CRP or ppGpp regulatory systems (see below), which do not affect *glgB* expression. The expression of the chromosomal *lacZ* gene in AC70R1 (*glgQ* mutant) and in the wild-type *E. coli* B strain was also similar, providing further evidence for the idea that *glgQ* affects a different regulatory system for the *glg* genes. In summary, *glgQ* and *glgR* mainly affect Transcript A and Transcript B, respectively.

Sigma Factor E σ 70 Transcribes *glgCAP*

The DNA sequences immediately preceding the 5'-ends of the three transcripts shown in Figure 4 are weakly related to consensus sequences for *E. coli* and *S. typhimurium* promoters. Although positively regulated promoters typically show weak similarity to the consensus sequence, it is also possible that one or more of the *glg* promoters is recognized via an alternative sigma factor. Therefore, the dependence of *glgC* expression on three sigma factors was tested in coupled transcription translation, using monoclonal antibodies that selectively inhibit transcription by specific and selective recognition of the sigma factors. A monoclonal antibody

Figure 4 Comparison of the 5' flanking regions of the *Escherichia coli* *glgC* transcripts with the consensus sequence of the *E. coli* *s-70* promoter. The *glgC* transcripts, A, B, and C are located respectively, at -60, -130, and -245 from the *glgC* initiation codon. The asterisks indicate the 5' termini of the transcripts. The best -10 and -35 regions are underlined.

directed against *E. coli* $\sigma 70$ inhibited up to 85% of the *glgC* expression, while an antibody directed against $\sigma 54$ or $\sigma 32$ did not inhibit expression of *glgC*, relative to *glnAP 2* ($\sigma 54$ -dependent) and *dnaK* ($\sigma 32$ -dependent) controls. Therefore, even though nitrogen limitation enhances glycogen synthesis *in vivo*, the expression of *glgC* is not regulated by the nitrogen starvation, $\sigma 54$ -dependent transcriptional controls. This conclusion agrees with the experimental result that *NtrC* and *NtrA* ($\sigma 54$) did not enhance expression of *glg* genes in S-30 experiments. The heat shock regulatory system ($\sigma 32$ -dependent) also appears to have no involvement in the control of *glgC* expression. Therefore, the major active form of RNA polymerase (*E. coli* $\sigma 70$) is apparently utilized for *glg* expression in the S-30 transcription translation system. However, the S-30 extracts used in the experiments were prepared from exponential cells to obtain optimal translational activity, and would not have contained endogenous activity from a sigma factor or an accessory factor synthesized in stationary phase. Therefore, expression via one or more other possible *glgC* transcripts may not have been detected by the S-30 experiments.

The Three Global Regulatory Systems Regulating Glycogen Biosynthesis

Glycogen biosynthesis is under the direct control of at least three global regulatory systems: catabolite repression (stimulation of *glgABC* expression by cAMP); stringent response (stimulation of *glgABC* expression by ppGpp); and repression of the *glgABC* expression by the *csrA* gene product, a 61-amino acid polypeptide.

Regulation by cAMP

The genes *cya*, encoding adenylate cyclase (EC 4.6.1.1), and *crp*, encoding cAMP receptor protein (CRP), are required for optimal synthesis of glycogen. Exogenous cAMP can restore glycogen synthesis in a *cya* strain but not in a *crp* mutant. cAMP and CRP are strong positive regulators of the expression of the *glgC* and *glgA* genes, but do not affect *glgB* expression. The addition of cAMP and CRP to S-30 extracts having *in vitro* coupled transcription-translation reactions and containing pOP12 as the genetic template, resulted in up to 25- and 10-fold increase in the expression of *glgC* and *glgA*, respectively. cAMP and CRP also enhanced the expression of *glgC* and *glgA* encoded by either plasmids or restriction fragments in *in vitro* reactions of protein synthesis. A restriction fragment that contained *glgC* and 0.5 kb of DNA from the upstream noncoding region of *glgC* was sufficient to permit cAMP-CRP regulated expression, suggesting that the *glgC* gene contains its own cAMP-regulated promoter(s).

Evidence of a CRP-binding site on a 243 bp restriction fragment from the upstream region of *glgC* was obtained using gel retardation analysis. There are also potential consensus CRP-binding sequences within the *glgC* upstream region preceding the *glgC* genes in both *E. coli* and *S. typhimurium*.

Regulation by ppGpp

Glycogen biosynthesis in *E. coli* is positively regulated by ppGpp as *relA* strains are glycogen-deficient. Expression of the *glgC* and *glgA* genes is stimulated by ppGpp. Expression of *glgC* in transcription-translation reactions increased three- to fourfold in the presence of ppGpp; *glgA* expression exhibited approximately a twofold enhancement. The expression of *glgB* was not affected by ppGpp.

Cyclic AMP and ppGpp also have independent effects on *glgCA* expression in *in vitro* transcription-translation experiments. Actually, their combined effects on *glgC* expression in such experiments can be synergistic. The addition of cAMP-CRP or ppGpp results in an increase of 6.3- or 1.6-fold, respectively, in the expression of *glgC* over the basal or unactivated level of expression, while their addition together leads to an 18.8-fold stimulation.

Evidence for positive regulation of *glgC* expression *in vivo* by ppGpp was obtained using the *glgC'-lacZ* translational fusion in pCZ3-3. This gene fusion was introduced into strains comprising an isogenic series that varied in basal levels of ppGpp owing to increasingly severe mutations in *spoT*. The *spoT* gene affects the level of ppGpp in the cell.

Regulation by *csrA* Gene Product via Regulating the *glg* Operons

A gene from *E. coli* K-12, *csrA*, encoding a negative factor for *glg* transcription has been identified. A mutant TR1-5 accumulated about 24-fold more glycogen than an isogenic wild-type strain. The gene affected by the TR1-5 mutation, *csrA* (for 'carbon storage regulator'), has been cloned, sequenced, and mapped on the *E. coli* genome, and some of its regulatory effects have been studied.

The TR1-5 mutation was also shown to affect glycogen levels by causing elevated expression of genes representative of both glycogen operons, *glgC* and *glgB*. Levels of ADP-Glc PPase expressed from the chromosome were approximately 10-fold higher in the TR1-5 mutant than in an isogenic *csrA* + strain in the stationary phase. The TR1-5 mutation affects glycogen levels and expression of the *glgB* and *glgC* genes in the exponential as well as the stationary phase.

The *csrA* gene also appears to regulate the expression of the gluconeogenic enzyme PEP carboxykinase (EC 4.1.1.38). Expression of a PEP carboxykinase operon fusion (*pckA*'-'*lacZ*) increased about twofold in exponential and stationary phases in the TR1-5 mutant, suggesting that gluconeogenesis may also be under negative control by *csrA*. When several isogenic strains were grown on synthetic media, it was found that *csrA* + and *csrA*::*kanR* strains (transductants with the TR1-5 mutation) were capable of growth on a wide variety of carbon sources. However, a strain that contained the functional *csrA* gene encoded on a multicopy (pUC19-based) plasmid pCSR10, could grow on glucose and fructose, but not on any of the gluconeogenic substrates – succinate, glycerol, pyruvate, and L-lactate. When strains were plated on a richer defined medium, support for growth of a pCSR10-containing strain using some gluconeogenic substrates, including acetate, as a major carbon source did occur. However, the pCSR10-containing strain formed only pinpoint colonies on succinate, whereas each of the other strains grew well. The *csrA* gene may affect succinate utilization or transport, independently of its effect on gluconeogenesis.

The *csrA* gene is located at 58 min on the physical map of the *E. coli* K-12 genome. It appears between the gene *alaS*, which encodes alanyl tRNA synthetase (EC 6.1.1.7), and the *serV* operon of tRNA genes, and is transcribed counterclockwise on the chromosome. The *csrA* ORF (open reading frame) encodes a 61-amino-acid polypeptide, which was strongly expressed from the plasmid pCSR10 in S-30 transcription-translation experiments. Deletion mapping experiments of the plasmid-encoded *csrA* gene demonstrated that it is required to mediate the inhibitory effects on the glycogen synthesis phenotype *in vivo*.

The *csrA* gene product negatively modulates posttranscriptionally by facilitating decay of *glgCA* mRNAs. The *csrA* gene product is a specific mRNA-binding protein binding to *csrB* RNA. Binding of the *csrA* gene product to *csrB* RNA inhibits the repression of the *glgCA* operon and the *glgB* genes. Since *csrB* RNA increases in stationary phase, it is believed that repression of the glycogen biosynthetic genes is relieved by the binding of *csrA* gene product by the *csrB* RNA.

Analysis of *glgC* transcripts by S1-nuclease protection mapping showed that the steady-state levels of four *glgC* transcripts (Figure 5) are elevated in the TR1-5 mutant and are severely depressed in a pCsr10-containing strain, indicating that *csrA* affects the transcriptional regulation of *glgC*.

Proposed Integrated Model for the Genetic Regulation of the Glycogen Biosynthetics Pathway in *E. coli*

Regulation of glycogen metabolism involves a number of factors coordinating the glycogen synthetic rate with the physiology of the cell. Genetic regulation of the glycogen biosynthesis pathway by cAMP and ppGpp allows *E. coli* to adjust its metabolic capacity for converting available carbon substrate into glycogen in response to the availability of carbon, energy, or amino acids, respectively.

Figure 5 Regulatory sites for transcription of *glgC*. The location of the CRP-binding region and the *glg* upstream transcription sites. Reviewed in Preiss J (1996) Regulation of glycogen synthesis. In: Neidhardt FC (editor in chief) *Escherichia coli and Salmonella typhimurium: Cellular and Molecular Biology*, 2nd ed., Vol. 1, pp. 1015–1024. Washington, DC: American Society for Microbiology.

Table 5 Genes affecting glycogen metabolism in *Escherichia coli*

Gene	Gene product	Map. site (min)	Comments
<i>Regulatory</i>			
<i>cya</i>	Adenylate cyclase	8	Regulates catabolite repression
<i>crp</i>	Cyclic AMP receptor protein	74	Regulates catabolite repression
<i>relA</i>	(p)ppGpp synthase I	60	Mediates stringent response and response to carbon/energy
<i>spoT</i>	(p)ppGpp3'-pyrophosphohydrolase	60	
<i>csrA</i>	6.8 kDa polypeptide (<i>csrA</i>)	58	Regulation of gluconeogenesis, <i>glgCA</i> , and <i>glgB</i> transcription
<i>glgQ</i>	Transacting factor (unidentified)	(?)	Transcriptional regulation of <i>glgCA</i> and <i>glgB</i>
<i>glgR</i>	<i>cis</i> -acting site	75	Transcriptional regulation of <i>glgCA</i>
<i>Structural Biosynthetic</i>			
<i>glgC</i>	ADP-Glc pyrophosphorylase	75	Synthesis of glucosyl donor
<i>glgA</i>	Glycogen synthase	75	α -1,4-Glucosyl transferase
<i>glgB</i>	Glycogen branching enzyme	75	α -1,6 branch chain synthesis
<i>Degradative</i>			
<i>glgP</i> (<i>glgY</i>)	Glycogen phosphorylase	75	Glycogen phosphorylase
<i>amyA^a</i>	α -Amylase	43	Glycogen hydrolysis
<i>glgX</i>	Glucan hydrolase/transferase	75	Isoamylase

^aRaha M, Kawagishi I, Muller V, Kihara M, and Macnab RM (1992) *Escherichia coli* produces a cytoplasmic α -amylase, AmyA. *Journal of Bacteriology* 174:6644–6652.

When cells are rapidly multiplying, the levels of the enzymes are repressed, and although the energy and carbon are available for glycogen synthesis, the glycogen synthesis rate is low. Upon nutrient deficiency, synthesis of ADP-Glc PPase and glycogen synthase are induced, and the capacity for glycogen synthesis is greater. The level of glycogen that is ultimately accumulated will be dependent upon carbon availability and is subject to allosteric regulation of the ADP-Glc PPase activity.

Genetic regulation thus determines the capacity for glycogen synthesis, and this can be distinguished from the regulation of absolute glycogen levels. For example, the glycogen biosynthetic enzymes are induced in stationary phase when cells are grown on enriched medium lacking glucose. Yet, glycogen synthesis does not occur because of lack of available carbon. But in media with excess glucose and limiting nitrogen, the expression of the genes for the biosynthetic enzymes is somewhat weaker as cAMP is at a lower level. However, the glycogen synthesis rate is relatively greater because of the carbon availability, and the conditions are such that allosteric activation occurs. Carbon availability allows the activator concentration to be relatively high, the ATP levels high while maintaining the AMP levels (the allosteric inhibitor) low.

Mutants that are affected in either negative (*glgR*, *glgQ*, *csrA*) or positive control systems (*cya*, *crp*, *relA*, *spoT*) for *glgCA* gene expression clearly demonstrate that the genetic regulation of the levels of glycogen biosynthetic enzymes is most important in determining the ultimate level of glycogen synthesized and accumulated under any given physiological condition.

The structural and regulatory genes involved in glycogen metabolism in *E. coli* are listed in Table 5; the effects of both positive and negative regulatory factors which control the expression of the *glg* genes of the glycogen biosynthetic pathway are listed. Many important questions remain to be solved, particularly the regulatory role of factor *csrA*. The physiological states to which the *csrA* regulatory system responds are yet to be determined. Moreover, the actual functions of *csrA* and many carbon starvation-induced genes in glycogen synthesis at the biochemical and molecular level also remain to be established.

Glossary

Archaeplastida Eukaryotic supergroup comprising photosynthetic organisms with a primary plastid. The group contains the Viridiplantae (green plants), red algae and glaucophytes.

Autospore Non-motile spore produced within a parent cell, and which has the same shape as the parent cell before release.

Diplohaplontic life cycle Sexual life cycle with two vegetative phases, one diploid and one haploid.

Haplontic life cycle Sexual life cycle containing only a haploid vegetative phase, with the only diploid cell being the zygote.

Isokont Flagella of a cell that are similar in structure, but may differ in length or behavior.

Mixotrophic Having partly autotrophic and partly heterotrophic nutrition.

Monophyletic group (clade) A group of organisms that contains all the descendants of a common ancestor.

Oogamous reproduction Sexual reproduction involving the fusion between a motile male gamete and a large, non-motile female gamete.

Paraphyletic group A group of organisms that has evolved from a common ancestor but which does not contain all descendants of that ancestor.

Phagotroph Heterotrophic or mixotrophic organism that ingests nutrients by engulfing solid particles.

Phragmoplast Array of microtubules oriented perpendicularly to the plane of cell division, determining the formation of the cell plate and new cell wall.

Phycoplast Array of microtubules oriented parallel to the plane of cell division, determining the formation of a new cell wall.

Picoplankton The fraction of the plankton composed by cells between 0.2 and 3 μm .

Plasmodesmata Cytoplasmic threads running through the cell wall and connecting the cytoplasm of adjacent cells.

Pyrenoid A spherical structure in the chloroplast, containing the enzyme RuBisCO, and associated with the formation of reserve polysaccharides.

Siphonein, siphonoxanthin Xanthophyll accessory pigments found in some prasinophytes and Ulvophyceae.

Zoospore A flagellate spore.

Abbreviations

CCW	Counter clockwise oriented basal bodies
CW	Clockwise oriented basal bodies
Cytb ₆ f	Cytochrome b ₆ f complex
DO	Directed oppositely oriented basal bodies
mya	Million years ago
PSI	Photosystem I
PSII	Photosystem II
UTC	Ulvophyceae, Trebouxiophyceae and Chlorophyceae

Defining Statement

Green algae are a large and ecologically important group of oxygenic photosynthetic eukaryotes. They are diverse in terms of species number, morphology, biochemistry and ecology. Together with the embryophytic land plants, they form the Viridiplantae or green plants (also known as Chlorobionta or Chloroplastida). The Viridiplantae comprise two clades: the Chlorophyta and the Streptophyta. The Chlorophyta include a wide variety of marine, freshwater and terrestrial green algae. The Streptophyta include freshwater green algae (also known as charophytes) and the embryophytic land plants. As such, the green algae with the exclusion of the land plants form a paraphyletic group. Monophyly of the green plants, on the other hand, is well established based on ultrastructural, biochemical and molecular data.

The green algae possess the following unifying traits, most of which are also shared with the land plants:

- Chloroplasts are enclosed by a double membrane, and include stacked thylakoids. Many species have pyrenoids, which are embedded in the chloroplast, penetrated by thylakoids, and surrounded by starch.
- Photosynthetic pigments include chlorophyll a and b, along with accessory pigments such as carotenes and xanthophylls.

- The most important reserve polysaccharide is starch, which is clustered around the pyrenoids or scattered through the chloroplast stroma.
- Many green algae are flagellate unicellular organisms, or have flagellate cells in some stage of the life cycle. Flagellate cells typically possess two (or a multiple of two) flagella, which are similar in structure (isokont), although they may differ in length or behavior.
- The region between the flagellum and its basal body (flagellar transition zone) is typically characterized by a star-shaped (stellate) structure, which is a nine-pointed star linking nine pairs of microtubules.
- Cell walls, when present, are generally composed of a cellulose fiber matrix.

Morphological and Ecological Diversity

The green algae contain around 500 genera and an estimated 15,000 extant species. They display several degrees of organismal complexity, ranging from the smallest unicellular eukaryote (*Ostreococcus*) to large and complex organisms. Vegetative morphological types include unicellular motile cells (flagellates), unicellular non-motile cells (coccoids), motile or non-motile colonies, unbranched or branched filaments, blades, parenchymatous thalli, siphonocladalean thalli (composed of multiple, multinucleate cells) and siphonous thalli (composed of a single, multinucleate giant cell) (Fig. 1).

Green algae are globally distributed from tropical to arctic regions, occurring in a wide range of aquatic habitats. They are widespread in freshwater environments, including lakes, ponds, streams, estuaries and wetlands. Some groups are abundant in marine environments, as plankton in nearshore or oceanic environments or attached in benthic coastal habitats. Green algae can form nuisance blooms under conditions of nutrient pollution in freshwater and marine environments. Several green algae are terrestrial or aerophytic, living on moist soil, rocks, and tree trunks. Some species occur in hypersaline environments, such as salt pans. Others have adapted to living in snow or ice. Several species engage in symbiosis with other eukaryotes, and some others are heterotrophic parasites.

The embryophytic land plants, which will not be discussed further in this article, include an estimated 400,000 species and are dominant in terrestrial habitats, although some species have adapted secondarily to freshwater or marine environments.

Cell Structure, Mitosis and Cell Division

The cell structure of green algae is essentially similar to that of other photosynthetic eukaryotes. Cells are enclosed by a plasma membrane, and contain a typical eukaryotic cytoskeleton, one to many nuclei, mitochondria, plastids, and other organelles. Many (but not all) green algae have a cell wall or other types of cell covering, such as organic body scales. Some green algal cells have a large vacuole. The fine structure of green algal cells, and processes of mitosis and cell division have been extensively studied, and some features, such as the ultrastructure of the flagellar apparatus, have been regarded as important characters for defining the main groups of green algae (Table 1).

Plastids

All green algae, with a few exceptions, are autotrophic with cells containing one to many chloroplasts. Chloroplasts have a double membrane and stacked thylakoids, which contain the photosynthetic pigments chlorophyll a and b. These pigments are generally not masked by differently colored accessory pigments, hence the characteristic green color of most species. However, some green algae (e.g., *Haematococcus* species, *Chlamydomonas nivalis*, and *Trentepohlia* species) accumulate photoprotective carotenoid pigments under high light conditions, masking the green color and appearing orange or red in color.

Chloroplast number and shape is highly variable. Most green algae have cells with a single chloroplast, which can be cup-shaped, ring-shaped, star-shaped, or plate-shaped. Giant celled green algae contain hundreds to millions of chloroplasts per cell, which can be isolated (e.g., in siphonous green algae), or organized in a netlike structure (e.g., in siphonocladalean green algae). Some green algae are heterotrophic (e.g., *Prototheca*, *Helicosporidium*, *Polytoma*) and contain non-photosynthetic plastids, with different metabolic functions. Several green algae are capable of supplementing photosynthesis by uptake of exogenous dissolved organic carbon, such as sugars, amino acids and other small molecules (osmotrophy), or by ingestion of living or dead particles (phagotrophy).

Most green algae have chloroplasts containing one to several pyrenoids. These structures are involved in the production of the photosynthetic reserve polysaccharide starch, which accumulates in plates around the pyrenoid (Fig. 2). The pyrenoid is often penetrated by several thylakoids. Starch formation also occurs elsewhere in the chloroplast, with starch granules scattered through the chloroplast stroma. Chloroplasts may also contain plastoglobules, which are lipoprotein particles coupled to thylakoid membranes and containing biosynthetic enzymes.

Flagellate cells often have an eyespot or stigma, which has a function in light perception, and determines the swimming direction of the cell. Depending on the intensity of the light, this can be either towards the light (positive phototaxis) or away from the light (negative phototaxis). The stigma is located inside the chloroplast, and comprises 1–8 rows of red-colored, carotenoid-containing globules, positioned between thylakoids (Fig. 2). The photoreceptor itself is rhodopsin (which is also the universal

visual pigment in animals), and is located in the plasma membrane. The function of the carotenoid globules is to shield the photoreceptor for strong light, to enhance the contrast, or to increase the light intensity.

The photosynthetic apparatus is highly similar to that of land plants. The primary reactions of photosynthesis are mediated by three protein complexes embedded in the thylakoid membranes of chloroplasts. These complexes are Photosystem II (PSII),

Table 1 General characteristics of the main groups of green algae

	Flagellar apparatus	Type of mitosis	Cell division	Morphology	Main habitat
Prasinophytes	Cruciate roots, some with MLS	variable	Furrowing	Unicellular	Marine planktonic, some freshwater
Trebouxiophyceae	Cruciate roots, CCW orientation	Semi-closed, non-persistent spindle	Furrowing, with phycoplast	Unicellular, colonial and simple multicellular	Freshwater to terrestrial
Chlorophyceae	Cruciate roots, CW or DO orientation	Closed, non-persistent spindle	Furrowing, with phycoplast	Unicellular, colonial and simple multicellular	Freshwater to terrestrial
Ulvophyceae	Cruciate roots (some with MLS), CCW orientation	Closed, persistent spindle	Furrowing, without phycoplast (one group with phragmoplast and plasmodesmata)	Unicellular to complex multicellular and giant-celled thalli	Mainly marine benthic, some freshwater or terrestrial
Charophytes	Asymmetric roots, MLS	Open, persistent spindle	Furrowing, some with phragmoplast and plasmodesmata	Unicellular to complex multicellular	Freshwater or terrestrial

the cytochrome b_6f complex (Cyt b_6f), and Photosystem I (PSI), which are connected in series through the photosynthetic electron transport chain.

Flagella

Most green algae are flagellates in their vegetative phase, or have flagellate cells in some stage of the life cycle (with few exceptions, such as the classes Zygnematophyceae and Palmophyllophyceae). Flagellate cells generally have two (or a multiple of two) flagella, which are generally inserted apically or subapically, or more rarely laterally (some prasinophytes and *Mesostigma*). The flagella of one cell are similar in structure (isokont), although they may differ in length or behavior. Few green algae have a single flagellum only (e.g., the prasinophytes *Micromonas* and *Monomastix*). A rare type of flagellate cells is characterized by a ring of flagella around the anterior end of the cell (stephanokont zoospores), and occur in asexual reproductive cells of Oedogoniales (Chlorophyceae) and *Derbesia* (Ulvophyceae).

The ultrastructure of green algal flagella has a $9 + 2$ arrangement of microtubules (axoneme), similar to flagella and cilia of other eukaryotes. Towards the base of the flagellum, just above where it emerges from the cell, the axoneme passes into a transition zone, which typically contains a structure that appears star-shaped (stellate) in cross section, and H-shaped in longitudinal section, visible using an electron microscope (Figs. 2 and 3). The flagella terminate inside the cell by basal bodies, which are composed of nine interconnected triplets of microtubules, and function as template for assembly of the flagellar axoneme. In most species of Chlorophyta, the flagella are anchored in the cell by four microtubular roots, which are connected to the basal bodies and run beneath the plasma membrane towards the bottom of the cell. These microtubular roots are symmetrically arranged in a cross (cruciate root system) when the cell is viewed from the top. Two of these roots contain two microtubules, the two others contain three to eight microtubules. In the Streptophyta and some prasinophytes the flagellar roots are arranged asymmetrical, with basal bodies positioned parallel to one another, and a broad band of approximately 60 microtubules (termed multilayered structure) anchoring the flagella in the cell. The relative position of the basal bodies varies between green algal groups, and can be positioned directed oppositely (DO), shifted clockwise (CW), counter clockwise (CCW), or lay parallel to each other. Other flagellar structures include two robust fibers that connect the flagella (present in most green algae), and a contractile striated fiber (rhizoplasts, common in the Chlorophyta, but rare in the charophytes) that connects the flagellar apparatus to the nucleus (e.g., *Chlamydomonas*) or the chloroplast (e.g., *Pyramimonas*).

Cell Walls

The cells of many green algae are covered by a cell wall. Other green algae either lack a cell wall (naked cells), or have other types of cell covering, such as organic body scales. Most green algal cell walls have a polysaccharide fibrils-matrix organization. Some species have cell walls composed of proteins only. In Chlorophyta, the cell wall is often composed of cellulose or chitin-like polysaccharides, xylan or mannan. The cell walls in prasinophytes are highly diverse. Many prasinophytes are naked (e.g., *Ostreococcus*, *Micromonas*), while others (e.g., *Pyramimonas*, *Nephroselmis*) are covered by one to several layers of organic body scales of various forms, including plate-like, hair-like, and complex, three dimensional structures. These organic structures are mainly composed of monosaccharides and produced within the Golgi apparatus. Cells of in the Chlorodendrophyceae are covered by a coherent wall composed of fused body scales. The Chlorophyceae include a wide diversity of cell walls ranging from cellulose-pectin complexes to walls composed of hydroxyproline-rich glycoproteins. Cell wall composition may remain identical or change during the cell life-cycle. Cell walls in the Ulvophyceae are also highly variable and are composed of cellulose, mannans, glucan, xylans, and sulfated and/or pyruvylated polysaccharides.

Fig. 3 Flagellar apparatus of *Chlamydomonas*. (A). Electron micrographs of a longitudinal section of the flagellar apparatus, and stellate structure of the transition zone in cross section. (B). Image top-right, by Lechtreck et al., 2013, licensed under CC BY 4.0, <https://doi.org/10.1186/2046-2530-2-15>.

In the charophyte classes Charophyceae, Zygnematophyceae and Coleochaetophyceae, cell walls contain assemblages of polymers similar to land plants, including cellulose, pectins, hemicelluloses, arabinogalactan proteins, extensin, and lignin.

Some members of the ulvophycean orders Bryopsidales (e.g., *Halimeda*) and Dasycladales (e.g., *Neomeris*) and some species of Charophyceae (e.g., *Chara*) are calcified by depositing calcium carbonate on the outside of the cells, forming a structural defense against grazing.

Mitosis and Cell Division

The processes of mitosis and cytokinesis are variable among green algae, but generally characteristic for the main groups (Table 1). During early prophase the basal bodies duplicate and move towards the poles of the future mitotic spindle where they function as centrioles. An unusual type of mitosis is present in species of Trebouxiophyceae, where the centrioles are not positioned at the poles of the mitotic spindle but at the metaphase plate of the chromosomes (metacentric mitosis). Mitosis is either closed, in which the nuclear envelope remains nearly intact during metaphase (characteristic for most Chlorophyta), or open, in which the nuclear envelope is broken down during nuclear division (characteristic for most charophytes). Also the behavior of the mitotic spindle during telophase differs among green algal groups. The spindle may degenerate quickly during telophase (non-persistent telophase spindle), or persist, resulting in a typical dumbbell-shaped telophase configuration.

Mitosis is followed by cell division (cytokinesis) in most green algae, except in groups with multinucleate cells (e.g., Cladophorales and Bryopsidales), where mitosis is uncoupled from cytokinesis. In most green algae, cell division is accomplished by furrowing (Fig. 4), in which a cleavage furrow is usually already present at the early prophase, but only develops further during telophase. Several groups of the core Chlorophyta (including the Trebouxiophyceae and Chlorophyceae) produce a phycoplast, which is an array of microtubules oriented parallel to the plane of cell division, determining the formation of a new cell wall, which is either formed through cell wall ingrowth or outgrowth. The charophytic classes Charophyceae, Zygnematophyceae and Coleochaetophyceae have a phragmoplast mediated cell division, in which an array of microtubules is oriented perpendicularly to the plane of cell division, determining the formation of the cell plate and new cell wall. This type of cell division usually results in the formation of plasmodesmata, which are channels through the cross walls that enable intercellular communication, and the development of complex tissues.

Reproduction and Life Cycle

Green algae reproduce sexually or asexually. Two main types of sexual life cycle are distinguished: haplontic and diplohaplontic (Fig. 5). In haplontic life cycles the vegetative body is haploid and produces haploid gametes that fuse and form the zygote, which is the only diploid phase in the life cycle. The formation of the zygote is immediately followed by a meiotic division. Diplohaplontic life cycles contain two free-living vegetative phases, one diploid and one haploid. The diploid sporophytic phase arises through the growth and division of a diploid zygote. The haploid gametophytic phase develops from a haploid meiospore, produced following meiosis in a cell of the diploid phase. The type of life cycle is taxonomically dependent, but also largely coincides with the environment (marine versus freshwater). The marine Ulvophyceae mainly have diplohaplontic life cycles, while most freshwater green algae have a haploid vegetative phase and a single-celled, often dormant zygote as the diploid stage. In several green algal groups (most prasinophytes, the early-diverging streptophytic lineages Mesostigmatophyceae, Chlorokybophyceae and

Klebsormidiophyceae, and several terrestrial members of the core Chlorophyta), sexual reproduction is apparently absent or has been rarely documented. Asexual reproduction occurs by binary fission, fragmentation or production of flagellate cells known as zoospores, or non-motile autospores.

Evolutionary History

Fossil Record

The green algae are ancient, and have played an important role in aquatic ecosystems for hundreds of millions of years. The oldest fossils attributed to green algae date from the Precambrian, but these fossils are scant, and their taxonomic affinities often

contentious. The resistant outer walls of prasinophytic cysts (phycmata) are well preserved in fossil deposits and especially abundant and diverse in the Paleozoic (ca. 250–540 mya). A filamentous fossil from middle Neoproterozoic deposits (*Proterocladus*, ca. 750 mya) has been attributed to siphonocladous green algae (Cladophorales), while the oldest reliable records of the siphonous seaweeds (Bryopsidales, Dasycladales) and stoneworts (Charophyceae) are from the Paleozoic.

Primary Endosymbiosis: Origin of the Archaeplastida

The green plants are one of the three clades of Archaeplastida, which originated following an endosymbiotic event, where a heterotrophic eukaryotic cell engulfed a photosynthetic cyanobacterium-like prokaryote (related to the present-day *Gloeomargarita lithophora*) that became stably integrated and ultimately evolved into a membrane-bound organelle, the plastid. This single event, which probably took place in the Palaeoproterozoic, around 1.9 billion years ago, marked the origin of oxygenic photosynthesis in eukaryotes and gave rise to three autotrophic clades with primary plastids: the Viridiplantae, the red algae (Rhodophyta) and the glaucophytes (Glaucophyta or Glaucocystophyta), which together form the Archaeplastida.

From this starting point, photosynthesis spread widely to other eukaryotes through secondary endosymbiotic events that involved the capture of either green or red algae by diverse non-photosynthetic eukaryotes, thereby transferring the primary plastids across distantly related eukaryotic lineages. Some of these secondary endosymbiotic partnerships have in their turn been captured by other eukaryotes, known as tertiary endosymbiosis. Three groups of photosynthetic eukaryotes now have plastids derived from a green algal endosymbiont: the chlorarachniophytes (Rhizaria), a small group of mixotrophic algae from tropical seas, the common freshwater euglenophytes (Excavata), which are common in freshwater, and some green dinoflagellates (Alveolata). A much wider diversity of photosynthetic eukaryotes, including the dinoflagellates, haptophytes, cryptophytes, chrysophytes, diatoms and brown seaweeds have obtained plastids from a red algal ancestor.

Diversification of the Two Green Plant Clades: Chlorophyta and Streptophyta

Molecular clock analyses, calibrated with the fossil record, have estimated the origin of the green algae around 1.2 billion year ago. An early split in the evolution of the green algae gave rise to its two main clades: Chlorophyta and Streptophyta (Fig. 6).

The Chlorophyta diversified as unicellular planktonic algae in the oceans of the Meso- and Neoproterozoic, and gave rise to the present-day prasinophytes, which form a paraphyletic group of early diverging clades of Chlorophyta. One of these prasinophytic lineages gave rise to the core Chlorophyta somewhere in the Neoproterozoic, which diversified in freshwater, terrestrial, and marine coastal environments, thereby evolving a wide diversity of morphologies, and different life cycle strategies.

The Streptophytic green algae or charophytes probably originated in the Neoproterozoic and diversified as unicellular algae in freshwater environments. The earliest charophytes were unicellular or simple multicellular organisms. Two important groups of multicellular charophytes diversified during the Paleozoic: the conjugating green algae (Zygnematophyceae) and stoneworts (Charophyceae). Ancestral charophytes invaded the land during the mid-Ordovician and early Silurian (480–430 million years ago), initiating the evolution of land plants.

Taxonomic Overview

Chlorophyta

The Chlorophyta include marine, freshwater and terrestrial green algae with diverse vegetative morphologies. Motile cells (when present) typically have a cruciate root system; a few groups have an asymmetrical flagellar apparatus. The orientation of the basal bodies – directly opposed (DO), counter-clockwise (CCW) or clockwise (CW) – has served as an important character for defining the main groups of Chlorophyta. Mitosis is generally closed, with a persistent or non-persistent spindle. Most species contain peroxisomes with the photorespiratory enzyme, glycolate dehydrogenase.

Prasinophytes

The early diverging clades of the Chlorophyta are collectively termed the prasinophytes (Fig. 6). Prasinophytes form a heterogeneous assemblage of mostly unicellular algae with diverse cell shapes that are naked, covered by walls and/or organic body scales; flagella are present or absent. Mitotic processes, biochemical features (including photosynthetic pigments and photorespiratory enzymes) are equally diverse, reflecting the paraphyletic nature of the group. Prasinophytes are predominantly found in marine environments, but several species also occur in freshwater. Most clades are relatively species-poor compared to the core Chlorophyta.

The **Mamiellophyceae** is the morphologically and ecologically most diverse clade of prasinophytes, including approximately 20 species. It includes the order Mamiellales and two smaller orders, Monomastigales (genus *Monomastix*) and Dolichomastigales (genera *Crustomastix* and *Dolichomastix*). The Mamiellales are comprised marine and freshwater flagellates and coccoid species, including *Ostreococcus* and *Micromonas*, which are among the smallest eukaryotes known (cell sizes of 0.5–2 µm), and form important components of marine picoeukaryotic communities. Indirect evidence for sexual reproduction in *Ostreococcus* and *Micromonas* is based on the occurrence of sex-related and meiosis-specific genes in their genomes.

Fig. 6 Phylogenetic relationships among the main clades of green algae, and indication of the main types of habitats and morphological forms.

The **Pyramimonadales** includes relatively large flagellates with 4, 8 or 16 flagella, with cells covered by complex body scales in multiple layers. About 50 species are known from marine and freshwater habitats. Some species of *Pyramimonas* and *Cymbomonas* are mixotrophic and possess a food uptake apparatus. Some species produce resting cysts (phycomata), which possibly result from sexual reproduction. These phycomata are abundant in the fossil record from the Cambrian onward.

The **Nephroselmidiophyceae** includes relatively large, asymmetrical flagellates with two laterally inserted, unequal and heterodynamic flagella. The flagellar apparatus is atypical in only having three flagellar roots. Cells and flagella are covered by diverse scales in multiple layers. About 30 species are known from marine and freshwater habitats. *Nephroselmis* is one of the few prasinophytes where sexual reproduction has been observed in culture.

The **Chloropicophyceae** comprises scale-less coccoid picoplanktonic algae surrounded by a thin cell wall. The class includes 6 known species, several of which are important components of marine phytoplankton, especially in moderately oligotrophic waters.

The **Palmophyllophyceae** is the deepest-branching clade of the Chlorophyta (Fig. 6), and include the marine coccoid Prasinococcales (e.g., *Prasinococcus*), and the Palmophyllales (e.g., *Palmophyllum*), which are macroscopic green algae growing in deep and low-light benthic marine habitats. These algae have a unique type of multicellularity, forming macroscopic bodies composed of isolated cells in a firm gelatinous matrix. Flagellate stages are absent.

Other prasinophytic clades include the **Picocystophyceae**, containing the coccoid species *Picocystis salinarum* from saline lakes, the **Pycnococcaceae**, including marine flagellates (*Pseudoscurfieldia*) and coccoids (*Pycnococcus*), and a couple of clades that are known only from environmental sequencing.

Core Chlorophyta

The core Chlorophyta include three large and diverse classes, Ulvophyceae, Trebouxiophyceae and Chlorophyceae (UTC), and two smaller classes, Pedinophyceae (marine and freshwater unflagellates) and Chlorodendrophyceae (marine and freshwater quadri-flagellates, including *Tetraselmis*) (Fig. 6). The UTC classes include a wide variety of morphological forms and are found in diverse environments. Trebouxiophyceae and Chlorophyceae mainly occur in freshwater and terrestrial habitats. Ulvophyceae are most abundant in benthic marine habitats. Several members of the Trebouxiophyceae and Chlorophyceae live as symbionts in protists (e.g., ciliates) and in animals (e.g., nudibranchs and anemones). These endosymbionts are commonly referred to as zoochlorellae, but belong to phylogenetically diverse lineages.

The classes Trebouxiophyceae, Chlorophyceae and Chlorodendrophyceae are characterized by cell division mediated by a phycoplast, which is absent in the Ulvophyceae.

Unlike the prasinophytes, where sexual reproduction has rarely been observed, the core Chlorophyta exhibit various sexual life cycle strategies. Marine members of the Ulvophyceae generally have diplohaplontic life cycles, while the freshwater Chlorophyceae and Trebouxiophyceae generally have a haplontic life cycle.

The **Trebouxiophyceae** include a wide diversity of about 900 species, including flagellates, coccoids (Fig. 1B), and colonies, as well as multicellular filaments and blades. Cells are generally uninucleate, are surrounded by a cell wall, but lack body scales. Motile cells have a cruciate flagellar root system and basal bodies in a CCW orientation. The sexual life cycle is haplontic, but many species reproduce asexually by zoospores or autospores. Species mainly live in freshwater or terrestrial environments, but some members (e.g., Prasiolales) occur in brackish or marine habitats. Several species are photosynthetic symbionts in various protists (e.g., ciliates), and invertebrates (e.g., scleractinian corals, sea anemones, sponges, green hydras). Species in several genera (e.g., *Trebouxia*, *Asterochloris*, *Asterococcus* and *Coccomyxa*) form symbionts with lichen fungi. Some species have lost photosynthetic capacity and have a heterotrophic free-living or a parasitic lifestyle. The heterotrophic alga *Prototheca*, which grows in sewage and soil, can cause infections in humans and animals known as protothecosis. *Helicosporidium* is an obligate parasitic alga found in the gut of insects. Genome data of *Chlorella variabilis*, an endosymbiont of the ciliate *Paramecium bursaria*, indicate that expansion of protein families containing protein–protein interaction domains and adhesion domains were involved in adaptation to symbiosis.

The **Chlorophyceae** include flagellates, coccoids and various colonial and multicellular forms. Approximately 3600 species are known, mainly from freshwater and to a lesser extent terrestrial habitats. Most species have uninucleate cells, with cell walls. Motile cells have cruciately arranged flagellar roots with basal bodies in DO or CW orientation. Sexual life cycle is generally haplontic, but many species reproduce asexually by cell division, or production of zoospores or autospores. Five main orders have been recognized. The species-rich and diverse orders Sphaeropleales (e.g., *Scenedesmus*, *Pediastrum*, *Hydrodictyon*) and Chlamydomonadales (e.g., *Chlamydomonas*, *Volvox*, *Dunaliella*) include some of the most common freshwater phytoplankton species. The Chlamydomonadales include two important model organisms. The unicellular flagellate *Chlamydomonas* (Fig. 1A) has been studied as a model for photosynthesis, chloroplast biogenesis, flagellar assembly and function, and cell cycle control. The colonial *Volvox* (Fig. 1C) has served as a model for the evolution of multicellularity, cell differentiation, and colony motility. The halotolerant species *Dunaliella salina* is among the most commercially important microalgae (see below). The smaller orders, Chaetophorales (e.g., *Uronema*), Oedogoniales (e.g., *Oedogonium*) and Chaetopeltidales (e.g., *Floydiella*) mainly include filamentous and colonial forms. Species in the Oedogoniales have a specialized form of oogamous sexual reproduction involving the production of stephanokont motile cells.

The **Ulvophyceae** include approximately 2000 species of marine macro-algae (green seaweeds) that grow in diverse coastal habitats, including rocky shores, coral reefs and tropical lagoons. A smaller diversity (about 200 species) occurs in freshwater or terrestrial habitats. Macroscopic forms include branched or unbranched filaments, blades or tubular forms, and giant-celled forms, including siphonocladous (Fig. 1H) and siphonous thalli (Fig. 1I). Cell division is by furrowing, without a phycoplast. Motile cells have cruciately arranged flagellar roots with basal bodies in a CCW orientation. Cell walls are diverse and are composed of cellulose, mannans, xylans, and sulfated polysaccharides. Ulvophyceae exhibit a wide diversity of life cycles. Species reproduce asexually or sexually. Sexual reproduction involves a heteromorphic or isomorphic diplohaplontic life cycle, or a haplontic life cycle. Monophyly of the Ulvophyceae is uncertain due to the lack of derived morphological and ultrastructural characters, and has not been convincingly established in molecular phylogenetic studies. Ten orders have been described of which the Ulotrichales, Ulvales, Cladophorales, Bryopsidales, Dasycladales, and Trentepohliales are the most speciose. The Ulotrichales and Ulvales mainly include multicellular thalli composed of uninucleate cells. A well-known representative of the Ulvales is *Ulva* or sea lettuce, which is globally distributed and can form extensive, free-floating blooms, known as green tides. *Ulva* is a model organism for studying morphogenesis in green seaweeds, and is also economically important in aquaculture. The Cladophorales include siphonocladous thalli, which are multicellular bodies composed of multinucleate cells with nuclei having a fixed position. The Bryopsidales and Dasycladales have siphonous thalli, which are macroscopic thalli composed of a single giant tubular cell with a single giant nucleus or thousands of nuclei, and cytoplasmic streaming enabling transportation of organelles, nutrients and transcripts across the giant siphonous cell. Well-known representatives of the Bryopsidales are *Caulerpa* and *Codium*, of which some species are invasive. The Trentepohliales is an atypical class with respect to ultrastructure and ecology,

occurring exclusively in terrestrial habitats. Several species of Trentepohliales (e.g., *Trentepohlia*) are symbiotic algae within lichens, and *Cephaleuros* includes pathogens of vascular plants.

Streptophyta

The Streptophyta include a paraphyletic assemblage of green algae (charophytes) and the land plants (Fig. 6). The morphology of charophytes ranges from unicellular to complex multicellular organisms. Species occur in freshwater or damp terrestrial habitats. Streptophyta share a number of unique traits, including motile cells (when present) with laterally inserted flagella, parallel basal bodies, asymmetrical flagellar roots, and one flagellar root with a characteristic multilayered structure. Mitosis is open with generally a persistent mitotic spindle. Motile cells generally lack body scales. Charophytes have peroxisomes with glycolate oxidase. Six classes of charophytes are recognized: Mesostigmatophyceae, Chlorokybophyceae, Klebsormidiophyceae, Zygnematoophyceae, Charophyceae and Coleochaetophyceae. The Zygnematoophyceae have been identified as the sister clade to the land plants based on molecular phylogenetic data (Fig. 6). The early-diverging classes, Mesostigmatophyceae, Chlorokybophyceae, and Klebsormidiophyceae, are characterized by cell division by furrowing, and apparent lack of sexual reproduction. The later-diverging classes, Zygnematoophyceae, Charophyceae and Coleochaetophyceae, are characterized by a phragmoplast-mediated cell division, presence of plasmodesmata (absent in Zygnematoophyceae), and sexual reproduction.

The Mesostigmatophyceae and the Chlorokybophyceae form the earliest-diverging lineages of the Streptophyta (Fig. 6). The Mesostigmatophyceae include the single species *Mesostigma viride* from freshwater habitats, characterized by motile cells covered with diverse organic body scales, and two laterally inserted flagella. The Chlorokybophyceae include the single species, *Chlorokybus atmophyticus*, which grows in freshwater or moist terrestrial environments, and forms packets of a few coccoid cells that produce asexual biflagellate zoospores with scales. The Klebsormidiophyceae are a small class of approximately 40 species from freshwater and terrestrial environments, characterized by unbranched filaments that produce biflagellate zoospores (e.g., *Entransia*, *Interfilum*, and *Klebsormidium*).

The Zygnematoophyceae or conjugating green algae are a large class of about 4000 species that are widespread and abundant in freshwater environments, damp terrestrial habitats, snow and ice. The group is morphologically diverse, including non-motile unicellular algae, small colonies, and branched or unbranched filaments. Flagellate stages are absent. Sexual reproduction occurs by a unique process of conjugation, involving fusion of amoeboid gametes, and production of thick-walled resistant zygotes. Traditionally two groups are distinguished, the Zygnematales and the Desmidiaceae, but this separation is not supported by molecular data. The Zygnematales contain unicellular or filamentous algae. Species of Desmidiaceae are usually unicellular algae composed of two semicells joined by a narrow isthmus (Fig. 1F). The highly diverse Desmidiaceae (desmids) are particularly characteristic of oligotrophic freshwater environments of low pH, such as bog pools.

The Charophyceae or stoneworts, include about 700 species of freshwater algae with complex macroscopic bodies composed of a main axis formed by large, multinucleate cells, and whorled branches. Growth is by an apical meristematic cell. Some species are calcified. Sexual reproduction involves fusion between a motile male gamete with complex morphology, and a large, non-motile female gamete (oogamous reproduction). Male and female gametes are surrounded by sterile cells. Well-known genera are *Chara* and *Nitella*. Stoneworts are well represented in the fossil record, with a large diversity extending back to the Silurian.

The Coleochaetophyceae is a small class of approximately 20 species from freshwater habitats (e.g., *Coleochaete*, *Chaetosphaeridium*). They include branched filaments and discoid pseudoparenchymatous or parenchymatous forms, with specific cells having hair-like extensions. Sexual reproduction involves fusion between a motile male gamete, and a large, non-motile female gamete (oogamous reproduction). Some species of *Coleochaete* have corticated zygotes that are retained on the mother plant from which they receive nourishment via placental transfer cells with wall ingrowths, similar to land plants.

Economic Importance

Several green algae are commercially harvested as sources of food or food supplements for humans and animals, or are potentially useful for the production of sustainable and renewable biofuels. Green microalgae are cultured for food supplements on industrial scales in open air systems or closed bioreactors. *Dunaliella salina* (Chlorophyceae) is among the most commercially important microalgae because of its high β -carotene production carotene. *Chlorella* species (Trebouxiophyceae) are sources of β -1,3-glucan. *Haematococcus pluvialis* (Chlorophyceae) is cultivated for its production of astaxanthin, a carotenoid that is used as an antioxidant food supplement or as a food coloring, for example in salmon aquaculture. Some green microalgae naturally produce high amounts of lipids, and have potential value for biofuels production, including *Dunaliella salina* and *Ettlia* (*Neochloris*) *oleoabundans* (Chlorophyceae), and *Botryococcus braunii* (Trebouxiophyceae). Seaweeds have been used as a food source for humans and animals, and as fertilizer for agriculture for centuries. Some marine green macroalgae are cultivated at a commercial scale for utilization in various food preparations, mainly in East and South East Asia, including *Ulva reticulata*, *Monostroma oxyspermum* (green laver or aonori), and *Caulerpa lentillifera* (sea grapes or lato). Species of Cladophorales (Ulvophyceae) have highly crystalline cellulose cell walls with unique physical properties, which have potential for various high-tech industrial applications, including reinforcement fibers, filter membranes, and conductive cellulose composites. Some seaweeds, including species of *Caulerpa* and *Halimeda*, are sold as ornamental algae for marine aquaria, which brings a risk for introduction of alien species.

Glossary

Commensalism Symbiotic relationship in which one species is benefited while the other is unaffected.

Diversity The degree of variation of organisms in an ecosystem based on the number of types of species present and their relative distribution in the assemblage.

Dysbiosis Imbalances in the composition of microbial communities colonizing the human body.

Evenness The distribution of organisms in a given community.

Microbiome The totality of microbes, their genomes, and interactions within a given ecosystem.

Microbiota The community of microbes residing in an ecosystem.

Mutualism Symbiotic relationship in which each of the organisms benefit.

Prebiotic Food compound refractory to the human digestive process that is selectively fermented by the gut microbiota resulting in specific changes in the composition and/or activity of the gastrointestinal microbiota, thus conferring benefit(s) on host health.

Probiotic Live microorganism that when administered in adequate amounts confers a beneficial health effect on the host.

Richness The number of types of species present.

Symbiosis Prolonged and close association between two or more different species.

The healthy human body is home to a vast number of phylogenetically and functionally diverse microbes assembled in communities of varying degrees of complexity. In fact, all external body sites and mucosal surfaces examined to date in healthy individuals are colonized by normally benign microorganisms in a typically symbiotic relationship. Compositionally distinct bacterial communities of commensal or mutualistic bacteria have been described for the skin (Grice and Segre, 2011), female reproductive tract (Ravel et al., 2010), oral cavity (Kolenbrander, 2000), and the respiratory (Lemon et al., 2010), as well as the gastrointestinal (GI) tract of healthy humans (Backhed et al., 2005). Since humans and their microbial colonists have coevolved, it is not surprising that a mutually beneficial relationship has emerged. Indeed, the ability of the human host to recognize and respond appropriately to the vast diversity and sheer numbers of organisms in sites such as the GI tract, which harbors up to 10^{14} bacterial cells, is a clear and impressive example of this coevolution. Advantages of this symbiotic relationship from a microbial perspective are easy to fathom: constant temperature, regular flow of nutrients, and protection from environmental insults. Benefits to the human host include a dramatically expanded metabolic capacity, vitamin production, pathogen exclusion, lymphatic development, and immune regulation, to name but a few (Kau et al., 2011). Most of the commensal bacteria that inhabit humans are well adapted to their respective niche; some are so highly specialized with respect to nutritional and environmental requirements that as of yet they have not been cultured under current standard laboratory conditions. Their presence in these sites is known only because of their detection using culture-independent methods that can identify microbial species without recourse to culture. With the advent and evolution of such technologies and several large-scale United States, European, and Asian funding initiatives to probe the diversity and function of microbial life associated with humans, we are beginning to better understand the interdependence of the human host and its microbial inhabitants, not least in the highly populated GI tract.

The Healthy Human Gut Microbiota

The notion that the bacteria residing in the intestine play an important role in human health and well-being is not new. Early attempts to identify and characterize these microbes were based on culturing bacteria from fecal samples. Using this approach, few species were identified and the microbial diversity within this niche appeared to be low. Microscopic analysis, however, indicated a much greater diversity suggesting that the majority of fecal bacteria could not be cultured under standard laboratory conditions (Suau et al., 1999). Following the advent of polymerase chain reaction (PCR) to amplify specific target genes of interest, microbial ecologists harnessed this technology to develop culture-independent techniques for microbial identification. This approach permitted identification of bacteria not based on their morphology and phenotypic characteristics, but on the sequence of particular biomarker genes. Moreover, using this approach, the identity and relative abundance of multiple organisms present in a mixed-species community of microbes could be determined, essentially generating a microbial fingerprint of the species present. A particularly useful genetic marker for the identification of bacteria is the 16S ribosomal ribonucleic acid (rRNA) gene (Woese and Fox, 1977). This gene encodes the small subunit of the bacterial rRNA, is thus present in all bacteria, and is not found in fungi or

This article is a reprint of M. Rauch, S.V. Lynch, Gut Microbiota in Human Health and Diseases, *Reference Module in Biomedical Sciences*, Elsevier, 2014.

higher organisms. The gene itself is useful as a bacterial biomarker since it possesses regions of gene sequence that are highly conserved across all bacteria; these regions flank highly variable sequence domains. The conserved regions may be used to design PCR primers to amplify regions of the 16S rRNA gene encompassing the hypervariable domains from the majority of bacteria in a given sample. The sequence of the variable domains in a given sample is then used to classify and identify the microbiota members present. The proportion of sequence reads for each organism in a given sample permits assessment of their relative distribution within that sample; these distributions can be compared across samples to determine relative contraction or expansion of specific groups of organisms across, for example, treatment groups. Recent advances in high-throughput technologies have dramatically accelerated microbiome research (Figure 1). Next-generation sequencing (NGS) and phylogenetic microarray analyses permit high-resolution, 16S rRNA-based microbiota profiles to be generated (Paliy and Agans, 2012; Petrosino et al., 2009). More recently, application of high-capacity NGS to DNA and RNA extracted from microbial communities has produced profiles of the microbial pan-genome and transcriptome, respectively (Maccaferri et al., 2011). Moreover, a variety of mass spectrometry approaches have been used to generate metabolic and proteomic profiles associated with microbial communities (Jacobs et al., 2009). Such approaches, particularly when applied in parallel, permit an unprecedented ability to analyze the composition, functional capacity, and expression profile of the organisms within these complex communities (Turnbaugh and Gordon, 2008). Their more recent application to human samples has fundamentally increased our understanding of how, at a local and systemic level, microbial communities that inhabit the human host impact human health and disease.

Structure and Composition

The human digestive tract – from the oral cavity to the rectum – is home to a variety of distinct, niche-specific microbial communities, including highly complex communities in the lower GI tract that contain all three domains of life – bacteria, Archaea, and eukaryotes as well as viruses. Even at a gross anatomical level, the various compartments of the digestive tract differ physiologically and, as a result, represent distinct ecological niches that house specific microbial populations (Figure 2). For example, a low burden and diversity of bacteria exists in the stomach and the upper small intestine due to low pH, rapid peristalsis, and high bile concentrations. In comparison, the number of prokaryotes residing in the colon far exceeds that of all other microbial communities associated with the body's surfaces and is estimated to contain over 70% of all the microbes in the human body and to outnumber human cells by approximately 10-fold (Figure 3) (Savage, 1977).

Although large with respect to number of organisms, the GI microbiota exhibits a relatively low level of diversity at the phylum level compared to other ecosystems such as soils that harbor similar bacterial densities (Figure 4). This suggests that strong selective pressures and coevolution have resulted in a highly specialized microbial consortium in the lower GI tract of humans. Indeed, only nine of the 55 bacterial Ribosomal Database Project defined phyla, and a single Archaea phylum has been described to date in this

Figure 1 State-of-the-art technologies commonly employed to profile microbial communities. A variety of high-throughput molecular approaches permit stand-alone analysis of phylogenetic membership and relative abundance (phylogenetic analysis), the pan-genome of the dominant members of the community (metagenomic analysis), as well as transcriptional (metatranscriptomic), metabolic (Metabolomic), and proteomic (metaproteomic) expression profiles of the assemblage. Parallel use of these approaches permit phylogenetic and functional characterization of the gut microbiota in unprecedented detail. NextGen Seq, next-generation sequencing; 2D-PAGE, two-dimensional polyacrylamide gel electrophoresis.

Figure 2 Niche-specific variation in microbial populations across physiologically distinct sites within the GI tract. The human GI tract consists of distinct partitions with characteristic physiological conditions that affect density, diversity, and stability of the microbiota present at each site. Commensals colonizing these compartments are well adapted to coping with exogenous factors such as peristaltic activity; food molecules and xenobiotics; gastric, pancreatic, biliary, and mucin secretions; as well as challenges by transient bacteria and antimicrobial peptides (Manson et al., 2008). Shown here are bacterial genera identified by culture-independent methods in samples obtained from the various sections of the GI tract. Data for this figure was obtained from Dewhirst, F.E., Chen, T., Izard, J., Paster, B.J., Tanner, A.C.R., Yu, W.-H., Lakshmanan, A., Wade, W.G., 2010. The human oral microbiome. *J. Diversity, stability and resilience of the human gut microbiota. *Nature* 489, 220–230 (colon). Note that data based on the construction of clone libraries may underestimate the bacterial diversity present.

niche. The phyla Firmicutes and Bacteroidetes dominate these microbial ensembles, at least in the GI tracts of humans residing in Western nations, and account for more than 70% of all bacterial taxa found. Phyla representing smaller proportions of these consortia include Actinobacteria and Proteobacteria (Dethlefsen et al., 2007; Ley et al., 2006; Turnbaugh et al., 2009a). Although few phyla are described in the GI tract, a relatively large diversity of genus and species are found in these communities. Conservative calculations estimate the presence of at least 800 bacterial species but recent studies suggest that the true number could be as high as 40 000 individual bacterial species residing in the human gut (Backhed et al., 2005; Claesson et al., 2009; Frank and Pace, 2008).

Figure 3 Relative frequency of microbial versus host cells and genes in humans. The GI microbiota is estimated to be composed of 10^{14} commensal bacteria, representing a 10-fold increase over the total number of human cells. Moreover, the sheer number of genes encoded by these species exceeds the number of genes identified within the human genome by about 100-fold. Given this diversity and the astounding metabolic capability contributed by the resident intestinal bacteria to human metabolism, it is easy to understand how significant they are to human health and how disturbances within the GI microbiota may induce or contribute to disease development.

Figure 4 Phylogenetic diversity of bacteria identified in the healthy human gut compared to agricultural soil. Shown is the numerical distribution of bacterial phyla in each habitat, based on data published by Eckburg et al. (2005) for the human gut and by Tringe et al. (2005) for the agricultural surface soil, both using clone libraries to assess diversity within these ecosystems. Reproduced from Turróni, F., Ribbera, A., Foroni, E., Van Sinderen, D., Ventura, M., 2008. Human gut microbiota and bifidobacteria: from composition to functionality. *Antonie Van Leeuwenhoek* 94, 35–50 with permission.

The composition of the intestinal microbiota varies significantly between hosts. Even though the human gut microbiota is most similar among family members, when compared to unrelated individuals, each individual's GI microbiome is unique and differs substantially from each other in the specific bacterial lineages present (even across pairs of fraternal twins) (Turnbaugh et al., 2009a). This suggests that environmental influences trump genetic forces in shaping these consortia. Because of these substantial differences between individuals, defining a core gut microbiota, shared by all humans, even within a defined population, e.g., in habitants of Western nations, has so far been elusive. However, metagenomic analyses, which permits a profile of the pan-genomic composition of a given microbial community to be determined, have indicated that despite interindividual compositional variation, an extensive, identifiable 'core microbiome' defined across human populations exists at the functional gene level (Turnbaugh et al., 2009a). This suggests a vast level of functional redundancy across microbial species that populate the GI tract and has identified core functions encoded by the microbiome that characterize healthy individuals. More recently, investigations have described at least two robust and distinct types of microbiomes (referred to as 'enterotypes') that are primarily distinguished by relative abundance of *Bacteroides* and

Prevotella genera (both belonging to the phylum Bacteroidetes). These two enterotypes differ in species composition and functional capacity and appear to span several nations and continents, although clearly larger studies including discrete populations with distinct microbial exposures are necessary to corroborate such findings (Arumugam et al., 2011; Wu et al., 2011).

Development and Function

The Development of the Gut Microbiota over the Course of Life

The GI tract of humans is presumed to be sterile at birth. The first microbial colonizers of the intestine are acquired during and immediately after birth when infants are inoculated with species in their immediate environment. Vaginally delivered infants acquire bacterial communities resembling their maternal vaginal microbiota, dominated by *Prevotella*, *Sneathia*, or *Lactobacillus* species. Cesarean-delivered infants harbor bacterial communities similar to those found on the skin surface, dominated by *Staphylococcus*, *Corynebacterium*, and *Propionibacterium* spp. and intestinal colonization by *Lactobacillus*, *Bifidobacterium*, and *Bacteroides* species is delayed (Dominguez-Bello et al., 2010). Hence, the mode of delivery during the birth process has a significant impact on the earliest microbial colonizers and community composition of the nascent gut microbiome. There is some evidence that these early-life pioneer microbial colonizers may substantially influence the trajectory of the infant GI microbiota development and influence predisposition to subsequent disease development in child- and adulthood (Johnson and Versalovic, 2012; Vael and Desager, 2009). For example, evidence indicates that early-life (3 weeks) fecal bacterial colonization patterns, specifically colonization with *Escherichia coli* and *Clostridium difficile*, are associated with a significantly higher risk of allergic disease development, while colonization with *Lactobacillus* and *Bifidobacteria* species lowered this risk (Kalliomaki et al., 2001a; Penders et al., 2006). Presumably, these physiologically distinct pioneer colonizers shape the GI ecosystem, perhaps through antimicrobial production or competitive colonization of the mucosal surface, leading to distinct patterns of colonization, which in turn impact immune maturation and subsequent allergic disease outcomes. However, more studies examining gut microbiota of infants from birth through the first few years of life are necessary to confirm this hypothesis.

Over the first year of life, the GI microbiome undergoes a temporal and seemingly chaotic program of development. Beginning with a low bacterial burden and few pioneering colonizers at birth, the numbers and types of bacteria that occupy this niche rapidly expands during early infancy and exhibits extensive variation across individuals (Palmer et al., 2007). Infant microbiota exhibit dramatic perturbation on antimicrobial administration characterized by reductions in bacterial density and profoundly altered community composition. Although these assemblages reassemble within a relatively short period, the short-term recovery is incomplete (Fouhy et al., 2012). Typically, the infant microbiome resembles an adult microbiome somewhere between 1 and 3 years of age, following the introduction of solid food. The healthy adult gut microbiota is relatively stable over time within individuals and surprisingly resilient toward disturbances that occur during the adult life. Nonetheless, disturbances such as antimicrobial administration have been shown to deplete the microbiome of species that are never again detected in these individuals (Dethlefsen and Relman, 2011). Therefore, it is conceivable, given the obvious evidence for functional redundancy in these consortia, that early perturbations during the period of immune development or indeed cumulative loss over time of key functions encoded by such species in established communities lead to instability and dysfunction within these communities and ultimately disease development. Certainly, there is evidence to support this hypothesis; children who receive antibiotics in the first year of life have been shown to be at a higher risk of atopy (Alm et al., 2008), while risk factors for the development of inflammatory bowel disease (IBD) include three or more antimicrobial administrations in the 24-month period prior to disease development (Shaw et al., 2011).

In addition to compositional and functional changes elicited through acute perturbations, the gut microbiota exhibits a gradual evolution over the lifetime of individuals, and, in the elderly, in parallel with increasing immune senescence. Senior (>65 years) stool microbiome differs from that of younger individuals in that the variability between individuals is even greater (O'Toole, 2012). Despite this, distinct changes at the phylum, genus, and, in particular, the relative abundance of *Clostridium* are common among most elderly. In seniors, the Bacteroidetes:Firmicutes ratio is substantially different from that of younger adults with a significantly lower proportion of Firmicutes. The GI microbiota of the elderly also varies significantly in the abundance of Proteobacteria, Actinobacteria (which includes *Bifidobacterium* spp.) and butyrate-producing Firmicutes including the genus *Faecalibacterium* (which includes *Faecalibacterium prausnitzii* thought to confer antiinflammatory properties) (O'Toole, 2012). Collectively, although the number of studies performed to date is relatively low, they are cobbling together a scenario of GI (and likely other sites such as skin) microbiome genesis, development, and evolution over the lifetime of a human. It is likely not coincidence that the observed alterations in immune function both in the very young and in the very old parallel the observed changes in these assemblages and provide further evidence, in human populations, that immune function is intricately interlaced with host microbial colonization patterns.

Functional Characteristics of the Intestinal Microbiota

The gut microbiota bestows a multitude of key functions to the human host (Figure 5). Their enormous metabolic potential plays an active role in energy harvest, in that they increase their host's caloric uptake not only by degrading indigestible dietary polysaccharides into absorbable monosaccharides but also by fermenting complex carbohydrates to short-chain fatty acids (SCFAs), which are then assimilated by the host, accounting for about 10% of daily energy intake in humans (Turnbaugh et al., 2006). The relevance of microbially derived SCFA production extends beyond energetic contribution to the host; SCFAs, such as acetate, butyrate, and propionate enhance the proliferation and differentiation of epithelial cells and modulate immune responses through their antiinflammatory properties (Tappenden and Deutsch, 2007). In addition to digestion of food, the intestinal microbiome also regulates energy storage and provides essential vitamins for the host (Backhed et al., 2004; Hill, 1997). Finally, the gut microbiota

Figure 5 Key functions that the enteric microbiota bestows upon the human host. The community of commensals colonizing the GI tract has a substantial influence on host physiology and human health. Their effects are observed both locally and at sites remote from the GI tract.

also contributes to the metabolism of xenobiotics, i.e., compounds usually foreign to a living organism, and as such influence directly or indirectly the efficacy of drugs (Haider and Turnbaugh, 2012).

Another key feature of the gut microbiota is prevention of pathogen overgrowth. Resident (autochthonous) intestinal bacteria inhibit invasion and colonization of foreign (allochthonous), potentially pathogenic bacteria by competing for the same nutrients and by occupying available niches in the gut, a phenomenon known as 'colonization resistance' (Stecher and Hardt, 2008). Disruption of the intestinal microbial community, for example, through (prolonged) antibiotic treatment, may result in a destabilized microbiota susceptible to invasion by obligate or opportunistic pathogens. For instance, epidemiologic data suggests that treatment with antibiotics is one of the predisposing factors for nosocomial infections with multiple-drug resistant *Enterococcus* species (Huycke et al., 1998). Antibiotic treatment has also been implicated in the etiology of GI infection with *C. difficile*, as is evident from patients suffering from *C. difficile*-associated diarrhea (DuPont et al., 2008). Indeed, mice exhibit enhanced susceptibility to *C. difficile* infection once their gut microbiota is perturbed with antimicrobials and these animals become highly contagious supershedders of this pathogen (Lawley et al., 2009). Similarly, mosquitoes (*Anopheles gambiae*), which naturally transmit *Plasmodium falciparum*, a protozoan parasite causing malaria in humans, become susceptible to this pathogen if their hindgut microbiota has been perturbed with antimicrobials (Dong et al., 2009). Collectively, these findings point to a role of the gut microbiome in protecting this niche from pathogen overgrowth and imply that loss of such species, particularly through antibiotic administration, results in increased susceptibility to infection.

The gut microbial community also has a significant impact on the development and morphology of the intestinal tract and contributes to angiogenesis and fortification of the intestinal epithelial barrier (Gustafsson et al., 1970; Hooper et al., 2001). Apart from the digestive tract, the enteric microbiota has also been shown to influence host physiology at extraintestinal sites. A relatively small but growing body of literature implicates a role of enteric bacteria on mammalian brain development (Heijtz et al., 2011) and hepatic lipid metabolism (Claus et al., 2011). Besides this, and with significant consequences for human health, is the intestinal microbiota's role in locally and systemically shaping and modulating the host's adaptive and innate immune system. Enteric microbes, through the secretion of metabolites and peptides, or via cell-associated ligands, constantly prime the innate immune system, thus facilitating a rapid response to pathogens (Clarke et al., 2010). Of particular importance is the GI microbiota's influence during the critical period of postnatal development and immune maturation. A growing body of evidence is focused on the complex interplay between initial events in GI microbiota assembly and the host's innate and adapted immune system and whether manipulation of these communities during this key developmental stage can impact the outcome of a number of inflammatory diseases such as asthma (Fujimura et al., 2010).

Influence of Diet on Microbiota Composition

From early life, the structural and functional composition of the intestinal microbiota is tremendously influenced by diet (Muegge et al., 2011; Turnbaugh et al., 2009b). Substantial differences exist in the gut microbiota composition of breastfed and formula-fed babies. The GI microbiota of breast-fed infants is dominated by lactobacilli and members of the genus *Bifidobacteria* (Adlerberth and

Wold, 2009). *Bifidobacteria* obtain their growth advantage from the utilization of complex human milk oligosaccharides, which are abundant in human milk, while *Lactobacillus* species utilize the abundant human milk sugar lactose as the primary carbon source. Both commensals shape the environmental conditions within the gut by increasing acidity through the production of lactic and/or acetic acid. This modulation of the intestinal niche likely defines which species cocolonize and may prevent colonization and overgrowth by pathogenic species for which these conditions are not optimal for multiplication. In contrast, formula-fed babies tend to have higher counts of Clostridia, *Bacteroides*, Enterococci, and Enterobacteriaceae such as *Klebsiella* and *Enterobacter* (Adlerberth and Wold, 2009). However, how these microbiome members shape the GI ecosystem from both a metabolic and immune standpoint remains to be determined.

Dietary habits continue to shape the GI microbiota throughout life. The fecal microbiota of European children raised on a typical high-fat, low-fiber 'Western' diet was found to differ significantly in richness and diversity from their African counterparts raised on a diet high in plant polysaccharides and fiber (De Filippo et al., 2010). Polysaccharidedegrading bacteria were enriched in the African study group and absent in the European cohort. Moreover, the relative ratio of the two dominant phyla detected in the GI microbiota (Bacteroidetes and Firmicutes) was also reversed: compared with western-diet fed children who exhibit a 3:1 ratio of Firmicutes to Bacteroidetes, African children possessed gut microbiota that were significantly enriched in Bacteroidetes and reduced in members of the Firmicutes. Additionally, significantly more SCFAs were found in samples from the latter population. This may allow these individuals to maximize energy intake from plant-based fibers while also protecting them from inflammation and infectious colonic diseases. More recently, a study has demonstrated that long-term dietary habits are strongly associated with microbial enterotypes (Wu et al., 2011). A diet rich in protein and animal fat is associated with a *Bacteroides*-driven enterotype. In contrast, the consumption of primarily plant-based carbohydrates is linked to an enterotype characterized by the abundance of *Prevotella*. A controlled-feeding intervention study showed that enterotype identity remains stable even though the microbiome composition changed detectably within 24 h of initiating a high-fat/low-fiber or low-fat/high-fiber diet, suggesting that the composition of the GI microbiome is largely defined by long-term dietary habits.

Enteric Microbes are Essential for the Development of Appropriate Immune Function

Evidence pointing to the importance of early GI colonization events on immunological maturation includes studies of germ-free mice, which demonstrated deficiencies in immune development in the absence of GI microbial colonization (Hrncir et al., 2008; Macpherson et al., 2000). Several other animal models and comparisons of human gut communities have reinforced the key role that appropriate microbial colonization plays in the development of the gut-associated lymphoid tissue and subsequent immune system development (Cebra, 1999; Hill and Artis, 2010). Intestinal microbial colonization instigates the innate as well as the adaptive immune system and triggers a multitude of responses that are critical for maintaining host-microbial homeostasis. Examples include stimulation of the production of effector molecules such as secretory IgA (Macpherson and Uhr, 2004), activation of the epithelial antimicrobial protein RegIIIg expression (Lehotzky et al., 2010), induction of proliferation of specific T-cell subset, e.g., proinflammatory T_H17 cells or antiinflammatory regulatory T (T_{Reg}) cells (Ivanov et al., 2009; Round and Mazmanian, 2010). IgA delays the gut microbiota diversification in infants and acts as a decoy ligand preventing colonization by pathogenic species, suggesting that IgA, particularly maternal IgA transferred through breast milk, may significantly impact early colonization events in the GI tract, and at least partially explain the microbial colonization patterns observed in breast-fed babies. T_H17 cells recruit neutrophils to the site of inflammation by producing interleukin-17, while T_{Reg} lymphocytes, when activated, counteract inflammatory mediators by suppressing immune response and inflammation.

The implications of influencing early events in GI microbiota assembly are underscored by the fact that maintenance of homeostasis between helper T lymphocytes expressing proinflammatory T_H1 cytokines, activating cellular immunity required for efficient response to intracellular pathogens (e.g., viruses), and counteracting T_H2 -associated cytokine expression, which stimulates a humoral antibody-based response, is essential to appropriate immune functioning. Humans are born with a bias toward a T_H2 -mediated immune response. The foundation for the T_H1/T_H2 balance is then laid during postnatal immune maturation in early infancy, the period in which the GI microbiota develops progressively until an assemblage resembling that of an adult emerges sometime after the first year. There is substantial evidence now indicating that a protective T_H1 response is induced by early-life exposure to microbes (Yoo et al., 2007). Importantly, it has been demonstrated that the presence of a GI microbiota is fundamental for establishing and maintaining the delicate equilibrium between these two subsets of effector T cells (Bowman and Holt, 2001; Mazmanian et al., 2005). The emerging hypothesis is that early stimulation of the immature immune system by a diversity of appropriate commensal microbes during the crucial stage of immune maturation is required for the development of a balanced immune system.

Diseases and Disorders Associated with Aberrations in the GI Microbiota

The development and progression of many digestive tract as well as systemic disorders and diseases are being linked to the GI microbiota (Fujimura et al., 2010). This is not surprising in view of the intimate relationship between the human body and its microbial symbionts and the multidimensional effects commensal gut microbes have on physiology and immune system development and maturation of the host. Diseases associated with the GI microbiota include the more obvious conditions such as colon cancer (Marchesi et al., 2011), irritable bowel syndrome (Salonen et al., 2010), and IBD (Nagalingam and Lynch, 2012) and also less obvious disorders such as obesity (Ley et al., 2006), type 1 diabetes (Wen et al., 2008), rheumatoid arthritis (Vaahantovu et al., 2008),

progression and severity of human immunodeficiency virus infections (Gori et al., 2008), development of nonalcoholic fatty liver disease (Spencer et al., 2011), cardiovascular disease (Wang et al., 2011), autistic spectrum disorders (Parracho et al., 2005), and allergy and asthma (Sjogren et al., 2009). Some of these diseases, such as obesity, IBD, or allergies, have been linked to aberrations in the composition of the gut microbial community, a condition called 'dysbiosis.' Dysbiosis is frequently accompanied by overgrowth of pathogenic microbial species, in conjunction with significant loss of microbial diversity and, presumably, as aforementioned, loss of key functional groups necessary to protect the mucosal surface and maintain metabolic and immune homeostasis. Factors that can impact the composition and stability of the GI microbiota include dietary changes, antibiotic use, psychological and physical stress, and altered GI tract peristalsis. For example, antibiotic therapy can give rise to antibiotic-associated diarrhea (e.g., due to *C. difficile* overgrowth). Current efforts by multiple research groups are examining how such perturbations may give rise to chronic disease.

Inflammatory Bowel Disease

The term 'inflammatory bowel disease' describes a range of GI disorders characterized by chronic inflammation of the mucosal layer of the digestive system. The two diseases under the umbrella of IBD, most commonly diagnosed in patients residing in Western nations are, ulcerative colitis (UC), typically restricted to the colon, and Crohn disease (CD), which can manifest anywhere along the digestive tract (from mouth to anus). The characteristic of UC is a contiguous inflammation of the superficial mucosal and submucosal intestinal layers. In contrast, CD patients exhibit healthy regions alternating with patches of inflamed tissue in a typically 'cobblestone-like' pattern. Transmural ulcerations causing fissures that may perforate the GI wall are also indicative for CD (Nagalingam and Lynch, 2012). Although the etiology of IBD remains unknown, perturbations in the GI microbial consortium have been associated with the onset and progression of the disease (Fava and Danese, 2011). More specifically, key members of the bacterial microbiota (i.e., *Clostridium* IXa and IV groups, *Bacteroides*, *Bifidobacteria*) are typically decreased in fecal samples from IBD patients while, in parallel, potentially detrimental bacteria (i.e., sulfate-reducing bacteria and *E. coli*) become more prevalent. The observed dysbiosis is concomitant with defective innate immunity and bacterial killing (i.e., reduced mucosal defensins and IgA, malfunctioning phagocytosis) and overaggressive adaptive immune response (due to ineffective T_{reg} cell populations and antigen-presenting cells), which are considered the basis of IBD pathogenesis (Fava and Danese, 2011). Moreover, at a functional level, bacteria producing butyrate such as *Faecalibacterium prausnitzii* are significantly depleted in the GI microbiota of IBD patients (Sokol et al., 2008). Butyrate and other SCFAs are known to have important antiinflammatory properties. Whether dysbiosis is the cause or result of IBD remains to be determined. Nonetheless, independent studies of microbiome collapse and the ability of specific GI species to induce subsets of inflammatory T cells associated with IBD implicate microbiome perturbation, failure of the community to reassemble, and pathogenic species proliferation as an obvious trigger for inflammation. This in turn likely further depletes microbiome diversity and protective functions within the community, permitting pathogen dominance and subsistence in the niche leading to chronic inflammation.

Enteric Microbes and Atopic Diseases

Atopic disorders such as allergies, allergic rhinoconjunctivitis, atopic eczema, and asthma are characterized by an imbalance in the T_H1/T_H2 equilibrium that is skewed toward an overexuberant T_H2 -mediated immune response (Robinson, 2010). The deficiency in mounting an appropriate T_H1 balance has been linked to a lack of early-life exposure to microbial antigens or inappropriate intestinal colonization (Okada et al., 2010). This paradigm is an extension of the 'hygiene hypothesis' first postulated by Strachan in 1989 in an attempt to explain the rising prevalence of asthma and childhood eczema in Western nations (Strachan, 1989). Several broad ecological studies have since demonstrated significant differences in the composition of the infant GI microbiota between populations with different rates of allergic disease development (Penders et al., 2007; Watanabe et al., 2003). More specifically, development of atopy was correlated with low GI microbial diversity and an increase in abundance of specific bacterial species such as *Clostridia*. In contrast, higher counts of *Lactobacillus* species have been described in the feces of infants with a reduced risk for the development of allergies (Sepp et al., 1997). As discussed above, multiple factors affect the composition of the infant gut microbiome, e.g., host genotype, mode of delivery (vaginal delivery versus Cesarean section), diet, and antibiotic therapy, and influence disease outcome later in life. Differences in the microbial succession patterns in the gut such as delayed intestinal colonization by *Lactobacillus*, *Bifidobacterium*, and *Bacteroides* species in infants born by Cesarean section may be the result of differences in initial community composition (e.g., lack of exposure to vaginal-associated *Lactobacillus* species in Cesarean-delivered babies), and these modifications will persist over time and ultimately may increase the likelihood of developing allergic traits. Supporting this hypothesis is the demonstration that 'like begets like,' in that communities with certain species present, e.g., *E. coli*, are more likely to permit 'invasion' by other similar species, e.g., *Shigella* species (Stecher et al., 2010). This suggests that assembly of the GI microbiota may be largely influenced by initial colonization events in this niche. Secondary to this argument is the supposition that if an aberrant microbiota establishes early in life during the critical period in which the immune system is primed by its microbial encounters, the resulting immune disequilibrium may also play a strong selective pressure in maintaining the abnormal microbiota and preventing colonization by beneficial species.

Microbiota Restoration

Although our understanding of the complex interplay between the human host and the intestinal commensal microbes as well as of the importance of maintaining the intricate balance between members of the gut microbiota is still in its infancy, various concepts

exist to treat or prevent dysbiosis and subsequent pathogen overgrowth or disease development by restoring microbiota homeostasis. Both fecal transplantation and probiotic supplementation have been used in an attempt to combat or prevent gut microbiota dysbiosis (Reid et al., 2011).

Fecal Transplantation

The transplantation of fecal material from a healthy individual into the GI tract of a patient recipient has been used to treat several intestinal as well as extraintestinal diseases with varying success. Donors are usually healthy relatives without a recent history of taking antimicrobial drugs. This is based on the assumption that their gut microbiome resembles most closely that of the patient prior to the development of dysbiosis. However, whether the patient's relationship to the donor affects outcome remains a contentious issue in the field. A fecal sample is collected from the donor and resuspended in a suitable diluent such as nonbacteriostatic saline prior to administration. The preferred route of transplantation is either through colonoscopy since this allows inoculation of the entire colon and ileum or through the application of a retention enema. Alternatively, the use of nasogastric or nasoduodenal tubes has also been described (Aroniadis and Brandt, 2013).

Fecal microbiota transplantation as an alternative to conventional antibiotic therapy has been highly successful for the treatment of chronic or recurring *C. difficile* infections (RCDI) (Gough et al., 2011). *Clostridium difficile* overgrowth and RCDI occur when the balance between the members of the gut microbiota is disrupted and pathogen exclusion is lost, e.g., due to the prolonged use of broad-spectrum antibiotics. Characteristic for patients suffering from RCDI is a low microbial diversity in the GI tract and a reduction in the numbers of Bacteroidetes and Firmicutes. Several reports describe that within 2 weeks of fecal transplantation, the recipient's intestinal microbiota closely resembles that of the donor. In fact, some recent studies have reported cure rates for RCDI using fecal microbiota transplantation at 92% (Gough et al., 2011).

Although relatively limited numbers of cases have been reported, the transplantation of fecal microbiota through retention enema has also successfully been used for the treatment of UC (Aroniadis and Brandt, 2013). Efficacy has been high with cessation of all symptoms within a few weeks after transplantation and without relapse. Remission was prolonged and up to 13 years postfecal transplantation in one case (Aroniadis and Brandt, 2013; Borody et al., 2003). The transplantation of fecal matter has also been described for the treatment of extraintestinal diseases such as autoimmune and neurological disorders (e.g., multiple sclerosis), obesity, chronic fatigue syndrome, and autism. However, the number of participants has been extremely small and the success rate highly variable. Yet, fecal microbiota transplantation for the restoration of appropriate diversity and, as a consequence, microbial function within the GI tract represents a viable and promising approach to the treatment of several refractory diseases.

Probiotics

Probiotics are defined as "live microorganisms which when administered in adequate amounts confer a beneficial health effect on the host" (Sanders et al., 2011). In contrast, a prebiotic is a food ingredient refractory to the human digestive process that is selectively fermented by the gut microbiota resulting in specific changes in the composition and/or activity of the GI microbiota, thus conferring benefit(s) on host health (Wallace et al., 2011). Although the concept of ingesting live microbes (primarily in the form of dairy products) to benefit human health and to abate diseases has been around for centuries, little is known about the immediate and prolonged effects probiotics have on the structure and function of the gut microbial community. By colonizing the gut and becoming part of the intestinal microbiota, probiotics are thought to alter the target microbiome, for instance, by introducing new metabolic capabilities such as the digestion of unusual carbohydrates. Colonization, however, may not be essential to induce shifts in the gut microbial community. Transient probiotic strains, when present in sufficiently high viable cell counts, may also significantly impact the structure of the intestinal microbiota by modulating key environmental factors such as pH or by producing antimicrobial substances (e.g., bacteriocins) or degrading proinflammatory cytokines.

Probiotic supplementation may improve IBD symptoms (e.g., induction or extension of disease remission periods) by restoring community composition and, thus, reconstituting functional capacity and the diverse beneficial effects the enteric microbes have on intestinal immune homeostasis. Several trials have been performed to test the efficacy of probiotic therapy on disease status and outcome of IBD. Some studies of probiotic supplementation indicate favorable outcomes in UC patients, while others report no significant improvement in the condition of CD patients (Haller et al., 2010). However, these preliminary findings are based on low-powered studies and the results have yet to be confirmed in controlled large-scale trials in which microbiome profiling is performed to determine the impact of bacterial supplementation on microbiome composition in patients with distinct disease and treatment courses.

Although several extrinsic and intrinsic factors likely contribute to the development of allergic disease, given the emerging importance of appropriate GI colonization in infancy, probiotic supplementation may be a useful strategy for the primary prevention of atopic disease. Several studies focus on newborns and infants and use various *Lactobacillus* strains as probiotic supplements. A randomized, placebo-controlled double-blind study of more than 100 newborns at risk for allergy development (based on family history) found that early feeding (daily for the first 6 months of life) of *Lactobacillus rhamnosus* GG (LGG) decreased the rate of atopic dermatitis at the age of 2 years by 50% (Kalliomaki et al., 2001b). In addition, follow-up studies after 4 and 7 years found that such effects are sustained past infancy, supporting the hypothesis that establishment of an appropriate GI microbial community during infancy via probiotic supplementation sets up a self-sustained community and presumably immune homeostasis that protects against allergic disease development (Kalliomaki et al., 2003, 2007). Others have, however, published

conflicting results. Kuitunen and colleagues studied the effect of postnatal supplementation for 6 months with a mixture of four probiotics (LGG, *L. rhamnosus* LC705, *Bifidobacterium breve* Bb99, and *Propionibacterium freudenreichii* ssp. *shermanii* JS) along with prebiotic galacto-oligosaccharides in preventing allergic diseases (Kuitunen et al., 2009). At the 2-year followup, they found that probiotic intervention significantly prevented eczema and in particular atopic eczema, but had no substantial effect on the cumulative incidence of all allergic diseases. After 5 years, there was also no more significant difference detectable in the frequency of eczema between the probiotic and the placebo groups suggesting that supplementation with probiotics achieved no allergy-preventive effect that extended to the age of 5 years. Interestingly, however, they found that Cesarean-delivered infants supplemented with probiotics had significantly less IgE-associated allergic disease at the age of 5 years compared to Cesarean-delivered babies who had received placebo only. The fact that Cesarean-delivered infants benefited most from probiotic supplementation suggests that their GI microbiota may more amenable to probiotic manipulation. The bacteria found in the GI tract of Cesarean-delivered newborns are usually skin-associated bacteria that are likely to be ill-equipped to successfully colonize the intestine and, thus, represent unstable consortia readily invaded by species more adapted to these niches. In another negative study, Rose et al. (2010) reported that oral supplementation with LGG of infants at high risk for atopy had no clinical effect on atopic dermatitis or asthma-related events. However, this study enrolled children who were already 6 months old and had at least two previous wheezing episodes. It is therefore possible that these children had passed the critical period of intervention and their relatively developed intestinal microbiota was already skewed toward an unfavorable composition.

Future Directions

Through the effort of several large-scale research programs launched in recent years in the United States, Europe, and Asia and by employing state-of-the-art technology, scientists have not only taken stock of the microbes colonizing various sites of the human body in unparalleled detail but also begun to uncover how the human microbiome and in particular the microbes residing in the GI tract shape human health and disease. Despite these significant achievements and largely because of substantial interindividual differences in the gut microbiome composition, there is no consensus yet on what defines a 'normal,' i.e., healthy GI microbiota, although key factors that influence these consortia, e.g., diet and antibiotic use, have been identified. More research is necessary to precisely determine key organisms and functional characteristics distinguishing healthy and unhealthy microbiomes and, moreover, to uncover the causal relationship between various disease and these assemblages. Of equal interest are long-term studies to describe the development of the human microbiome over the life span of an individual and to assess how changes correlate with health and disease states. Finally, attempts to determine how lifestyle and environmental exposures, particularly those associated with Western or developing nations, affect the composition and function of the microbiome and contribute to disease burden are of obvious importance and require large studies across geographically and demographically distinct populations. Findings from such studies will likely provide transformative insights into diseases and disorders more prevalent in one population compared to others and open up novel approaches or improve upon existing therapeutic strategies to treat disease.

Glossary

Biofilm A surface-associated community of bacteria, usually surrounded by an exopolysaccharide matrix.

Competence The ability to take up extracellular DNA.

Lipooligosaccharide (LOS) Component of the outer membrane of the Gram-negative mucosal pathogens. Differs from the lipopolysaccharide (LPS) of most other Gram-negative in that LOS lack the repeating oligosaccharide component that comprises the O antigen. LOS are important in virulence.

Phase variation Reversible alteration of surface antigens and virulence factors that often aids in the evasion of the immune response.

Pili Filamentous projections from the cell surface that consist of a repeating protein subunit. Often involved in adherence, biofilm formation, and twitching motility.

Planktonic Single bacterial cells capable of floating in liquid that do not reside within a biofilm.

Sialic acid Carbohydrate that is acquired from the host and used in the decoration of the LOS and biofilm matrix of nontypeable *Haemophilus influenzae* (NTHi). Sialic acid confers a net negative charge to the bacterium and protects from complement-mediated killing.

Abbreviations

ABC	ATP-binding cassette
cAMP	Cyclic AMP
ChoP	Phosphorylcholine
COPD	Chronic obstructive pulmonary disease
CRP	cAMP receptor protein
ECM	Extracellular matrix
Hep	Heptose
Hib	<i>Haemophilus influenzae</i> serotype B
KDO	Ketodeoxyoctanoate
LOS	Lipooligosaccharide
LPS	Lipopolysaccharide
NAD	Nicotinamide adenine dinucleotide
Neu5Ac	Sialic acid
NTHi	Nontypeable <i>Haemophilus influenzae</i>
PAFR	Platelet activating factor receptor
PRP	Polyribosylribitol phosphate
PTS	Phosphoenolpyruvate:fructose phosphotrans-ferase system

[☆]*Change History:* December 2014. WA Szymczak and MH Levi changed a considerable amount of the text and the sections. Updated references and added 1 figure.

This article is an update of J.W. Johnston, M.A. Apicella, *Haemophilus influenzae*, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 153–162.

Defining Statement

Haemophilus influenzae is a Gram-negative, strict human pathogen. Despite the development of a vaccine against the most invasive serotype of *H. influenzae*, serotype B (Hib), infections caused by strains with other capsular serotypes, nontypeable *H. influenzae* (NTHi), and Hib infection in unvaccinated populations remain to be of major medical importance. The features of *H. influenzae* that contribute to colonization, persistence, and invasion are discussed within.

Introduction

In 1892, Richard Pfeiffer isolated small, straight Gram-negative bacilli from the nasopharynx of patients with influenza during a pandemic. The frequency of occurrence of this organism in patients with influenza and its alleged virtual absence in normal individuals led to the erroneous conclusion that this bacillus was the cause of the influenza pandemic of 1890 and thus the organism was named the 'influenza' bacillus. In 1920, the bacterium was designated a species of *Haemophilus* by Winslow et. al.

H. influenzae gains access to the respiratory tract after host inhalation of respiratory droplets or contact with secretions containing the bacterium. NTHi strains of *H. influenzae* lack the genes for encapsulation and frequently colonize the upper respiratory tract without causing disease. However, NTHi can cause acute conjunctivitis, acute otitis media, acute sinusitis, exacerbation of chronic obstructive pulmonary disease (COPD) and pneumonia in some individuals. In contrast, encapsulated strains of *H. influenzae* are rarely recovered from the nasopharynx of asymptomatic individuals and are more likely to invade the bloodstream. There are six antigenically distinct serotypes (a through f) of encapsulated *H. influenzae*. By 1935, it was recognized that Hib strains were the most common isolate of *Haemophilus* isolated from blood and CSF.

In 1987, the first glycoconjugate vaccine for use in humans against Hib was licensed. Vaccination has significantly reduced the incidence of Hib meningitis and also provided a framework for the development of vaccines against other infections requiring the enhanced antibody response that can be elicited by conjugation of a protein carrier to bacterial carbohydrates. In 1995, the genome sequence of *H. influenzae* KW-20 Rd was published, becoming the first free-living organism to have its genome completely sequenced. Access to the full genome of the organism continues to drive research into the virulence factors of the species today.

Taxonomy, Culture Conditions, and Laboratory Testing

H. influenzae is a member of the family Pasteurellaceae in the Gamma subdivision of Proteobacteria. The organisms are non-spore forming, non-motile, pleomorphic Gram-negative coccobacilli. On Gram stained smears, the organism may be overlooked because of its small size and inconsistent uptake of counterstain.

H. influenzae is a facultative anaerobe and a strict human pathogen. The bacterium requires protoporphyrin IX (factor X) and nicotinamide adenine dinucleotide (NAD, factor V) as supplements for aerobic growth. *H. influenzae* will grow on chocolate agar, which contains adequate amounts of factor X and V. The organism grows optimally at 35–37 °C in the presence of 5–7% CO₂. Colonies 0.5–2 mm in diameter can be seen 24–48 h after inoculation. The colonies are smooth, low, convex, grayish and translucent. In contrast, blood agar plates do not support the growth of the organism because most NAD is sequestered intracellularly within red blood cells and blood contains enzymes that degrade extracellular NAD. The organism will only grow on blood agar plates as tiny, pinpoint 'satellite' colonies around organisms such as *Staphylococcus aureus* that release NAD and a toxin into the media that lyses red blood cells.

Factor X and V requirements along with sugar fermentation and utilization of other biochemical substrates can be used to distinguish *H. influenzae* from other species of *Haemophilus* that colonize the upper respiratory tract. *Haemophilus parainfluenzae*, which comprises approximately 75% of the *Haemophilus* species found in the nasopharynx, only requires V factor for growth and can ferment mannose. Although *H. parainfluenzae* rarely causes disease, the bacterium has become increasingly recognized as a cause of endocarditis. *Haemophilus haemolyticus*, another nasopharyngeal organism that rarely causes disease can be more difficult to distinguish from *H. influenzae* as it also requires both X and V factors and biochemical utilization is similar. Differentiation is often based on the ability of *H. haemolyticus* to hemolyze blood agar plates, but 10–40% of *H. haemolyticus* strains are not hemolytic, thus misidentification is common.

Other species of *Haemophilus* that can cause disease in humans include *Haemophilus influenzae* biogroup *aegyptius* and *Haemophilus ducreyi*. *H. influenzae* biogroup *aegyptius* can cause purulent conjunctivitis, or 'pink eye,' in children and is also the causative agent of Brazilian purpuric fever, a systemic illness that occurs subsequent to conjunctivitis. Like *H. influenzae*, *H. influenzae* biogroup *aegyptius* requires both X and V factors for growth but can be distinguished because it does not produce indole. *H. ducreyi* causes chancroid, a sexually transmitted infection characterized by a painful genital ulcer. The organism only requires factor X for growth, but isolation of *H. ducreyi* can be difficult because the organism dies quickly once removed from the lesion and recovery of the organism requires the preparation of media that limits growth of other bacterial species and inhibits the effects of toxic substances carried over from the genital ulcer. Two human pathogens formerly classified as *Haemophilus* species, *Haemophilus aphrophilus* and *Haemophilus paraphrophilus*, have been re-categorized as one species, *Aggregatibacter aphrophilus*. Although *A. aphrophilus* rarely causes disease, it can be a cause of sepsis, bone and joint infection, spondylodiscitis, and

endocarditis. The bacterium is a member of the HACEK group (*Haemophilus parainfluenzae*, *Aggregatibacter* spp., *Cardiobacterium* spp., *Eikenella corrodens*, and *Kingella* spp.). These organisms are found in the nasopharyngeal and oral cavities and all can cause endocarditis. *A. aphrophilus* does not require X or V factors for growth. Other *Haemophilus* species, *H. suis*, *H. somnus*, *H. avium*, *H. equigenitalis*, *H. gallinarum*, and *H. paragallinarum*, are pathogens of animals.

Haemophilus species isolated from blood or other sterile sites indicate disseminated infection and should always be considered significant. *Haemophilus influenzae* isolated from specimens originating from the lower respiratory tract in predominating amounts, from tympanocentesis fluid, or from the eye may also be clinically significant. *Haemophilus influenzae* can be identified directly from CSF or urine specimens using a commercially available latex agglutination assay, but the assay lacks both sensitivity and specificity so it is not routinely performed in most clinical laboratories. Once recovered on media, the bacteria can be identified by X and V factor requirements as described above and by commercially available biochemical-based identification systems. MALDI-TOF mass spectrometry has emerged as a rapid means to identify bacterial species. MALDI-TOF identification can be used to identify *Haemophilus* species from plated media and can also be used to directly identify organisms isolated from positive blood culture bottles, but the ability to accurately identify *H. haemolyticus* is dependent on the instrument and reference database that is utilized. 16S ribosomal sequencing can also be employed for *Haemophilus* identification, although this is not performed routinely in most clinical laboratories. If further strain typing is needed to investigate strain epidemiology, pulsed-field gel electrophoresis is the gold standard.

An agglutination assay using polyclonal antisera is usually performed to determine if the bacterium is encapsulated and if so, the serotype. However, molecular methods that detect the Cap locus are more accurate at differentiating unencapsulated versus encapsulated strains. Clinically significant isolates of *H. influenzae* should also be tested for the ability to produce β -lactamases. Production can be assessed by performing a rapid chromogenic test for the ability to degrade a nitrocefin substrate. If positive, the isolate should be considered resistant to amoxicillin and ampicillin, but will usually remain sensitive to β -lactam/ β -lactamase inhibitors, cephalosporins, and carbapenems. Further susceptibility testing may also be necessary depending on the source of the isolate and local epidemiology. For example, isolates of *H. influenzae* can be resistant to ampicillin as a result of altered penicillin binding proteins, not β -lactamase production. These strains are rare in the US but are increasing in Japan. Resistance to levofloxacin is also low in the United States but has increased in Taiwan between 2004–2010. Approximately 20% of *H. influenzae* strains in the US are resistant to trimethoprim sulfamethoxazole, and *H. influenzae* is intrinsically resistant to macrolide-lincosamide-streptogramin B antibiotics.

Infections Caused by *H. influenzae*

Meningitis and Sepsis

Prior to the development of the vaccine, *H. influenzae* was the commonest cause of meningitis in children between the ages of 2 months and 2 years, with 95% of these cases attributable to Hib. In the United States, introduction of the protein-conjugated Hib capsular vaccine has significantly reduced the incidence of Hib meningitis in both children and adults since 1990 by >95%. Today, the incidence in the United States is less than 1 case per 100 000 children and infection is usually present in children who were only partially or not vaccinated. In adults, *H. influenzae* is a relatively uncommon cause of meningitis. Hib meningitis in adults is usually associated with previous head trauma, neurosurgery, sinusitis, otitis, or CSF leak. The clinical presentation of meningitis due to *H. influenzae* is otherwise no different from that of meningitis due to other bacterial pathogens. Hearing impairment and neurological sequelae will develop in 15–30% of individuals with meningeal disease. In the United States, the Hib vaccine series is begun at 2 months of age. Vaccination is also recommended for adults with predisposing conditions such as splenectomy, HIV, primary immunodeficiency, or immunosuppression resulting from cancer treatment or stem cell transplant.

In countries with high Hib vaccination rates, NTHi causes the majority of *H. influenzae* infections resulting in bacteremia. Patients with invasive disease usually have other co-morbidities due to conditions such as alcoholism, cardiopulmonary disease, HIV, immunosuppression, complement deficiency, recurrent bacterial infections, viral infection or cancer. In adults, the respiratory tract is usually the source of NTHi. In addition to Hib, the other encapsulated strains are also capable of causing sepsis and meningitis. In North America and Europe, serotype F strains are responsible for most cases of invasive disease caused by encapsulated strains. The incidence of serotype A invasive infections is also believed to be increasing in some areas. In Alaska, serotype A invasive disease was not reported in the pre-Hib vaccine era, but beginning in 2002, serotype A has emerged as a major cause of invasive disease in native children.

Haemophilus influenzae, most frequently Hib, can cause cellulitis and septic arthritis. Hib septic arthritis occurs primarily in children less than 2 years of age and cellulitis caused by Hib is also more commonly seen in young children. *H. influenzae* biogroup *aegyptius* is the cause of Brazilian purpuric fever. This illness, first recognized in Brazil, is a serious systemic illness in children. The disease, which is preceded by purulent conjunctivitis, is characterized by fever, petechia, purpura, and shock.

Pneumonia and Tracheobronchitis

Immunization has reduced the carriage of Hib in the nasopharynx, and Hib is a rare cause of pneumoniae today. However, NTHi remains only second to *Streptococcus pneumoniae* as a cause of community-acquired bacterial pneumonia. Approximately 80% of *Haemophilus* species causing pneumoniae are NTHi. Disease can be caused by strains of NTHi that have asymptomatically

colonized the upper respiratory tract for months or from the acquisition of new NTHi strains. Unlike encapsulated strains, NTHi are antigenically and genetically diverse, and some strains are associated with a greater ability to cause disease because of the virulence determinants possessed. Host factors are also associated with the development of disease, as patients with infections caused by NTHi are generally elderly and have a history of chronic lung disease or a long smoking history. Patients with HIV infection have been shown to be susceptible to serious respiratory infection due to Hib and NTHi. The clinical features are indistinguishable from those of other bacterial pneumonias, with fever, cough, and purulent sputum, usually of several days' duration. The radiologic picture is not distinctive, showing either lobar or patchy involvement. HIV-infected patients may have an increased rate of bacteremia accompanying respiratory infections with Hib.

The role of NTHi as an etiologic agent in acute exacerbations of chronic bronchitis resulting from chronic obstructive pulmonary disease (COPD) was once controversial, but is generally accepted today. The organism can be found in serial cultures of sputum in the majority of patients with chronic bronchitis during quiescent periods. Thus, the mere presence of the organism does not imply a pathogenic role for the organisms in this setting. However, the isolation of NTHi from sputum during exacerbations, the development of serum antibodies to NTHi after exacerbations, and the response of patients to antibiotics strongly suggests that NTHi is the etiologic agent in many acute exacerbations of chronic bronchitis. In addition, a study of an unlicensed whole-cell NTHi vaccine reduced the number and severity of COPD bronchitis episodes. In March of 2014, a new 10-valent pneumococcal conjugate vaccine that includes NTHi protein D as a carrier protein was licensed. Whether the vaccine will protect against NTHi pneumonia and invasive infection in COPD patients remains to be determined.

Otitis Media, Sinusitis and Conjunctivitis

Otitis media is the most common cause for office visits resulting in antimicrobial treatment and surgery for children. NTHi is the second leading cause of acute otitis media in children behind *S. pneumoniae* and also causes disease in adolescents and adults. The peak incidence for disease is between 6 and 24 months of age. By 3 years of age, more than two-thirds of children have had one or more episodes of acute otitis media. Australian Aboriginal and American Inuit children are especially susceptible to NTHi otitis media. A high incidence of hearing loss is common in these populations. Preliminary studies suggest that the new 10-valent pneumococcal NTHi-D vaccine may reduce acute otitis media caused by NTHi. In an efficacy study of the 11-valent prototype NTHi-D vaccine, there was 57% efficacy against pneumococcal and 35% efficacy against NTHi-mediated otitis media.

Encapsulated strains of *H. influenzae* also cause acute otitis media. In one study in Thailand, where <5% of the population is vaccinated, 62% of *Haemophilus* isolates from tympanocentesis fluid were Hib. Another study in Venezuela also demonstrated that 31% of *Haemophilus* isolates causing acute otitis media were caused by encapsulated strains.

H. influenzae can be a cause of conjunctivitis and sinusitis. Bacterial conjunctivitis is more common in children than in adults and is caused by NTHi in approximately 50% of cases. NTHi conjunctivitis can occur simultaneously with NTHi-mediated otitis media. In children with acute purulent sinusitis, *S. pneumoniae* or *H. influenzae* often predominate over other nasopharyngeal flora.

Obstetrical and Neonatal Infections

Obstetrical infections due to *H. influenzae* are a serious complication in pregnancy as both the mother and the child become infected, and there appears to be maternal–fetal transmission. The isolates are almost invariably NTHi. Symptoms in both mother and child occur within 24 h of birth and there is a high frequency of prematurity associated with these infections. Infant mortality is high.

Adult Epiglottitis

Hib is a cause of epiglottitis in children (usually age 2–7) and in adults. In one large retrospective review, the incidence of acute epiglottitis in adults was 9.7 cases per million population. The average age of the patients was 44 years with an equal sex distribution. Patients presented with an elevated temperature, sore throat (90%), dysphagia (80%), respiratory difficulty (45%), and hoarseness or drooling. Indirect laryngoscopy visualization of an inflamed epiglottis has proven to be the more reliable in making the diagnosis (positive in 86% of cases) than soft tissue X-rays of the neck. Laryngoscopy can induce laryngospasm, particularly in children, and clinicians should be prepared to maintain the airway with tracheostomy when this procedure is performed. Mortality in this study was 7%, with all deaths related to airway obstruction. Based on this complication, it has been suggested that an airway should be established at the time of presentation rather than waiting for a worsening clinical picture. Antibiotic therapy is primarily directed against *H. influenzae*, group A *Streptococci*, and *S. pneumoniae*, which have also been implicated as etiologic agents in adult epiglottitis.

Other Infections

A variety of other less common manifestations of *H. influenzae* infection in adults have been documented, primarily in the form of case reports. These include empyema, pericarditis, osteomyelitis, endocarditis, cholecystitis, intra-abdominal infections, urinary tract infections, mastoiditis, and aortic graft infection.

Virulence Factors

H. influenzae possesses many virulence factors that are modulated in a complex manner to aid in colonization, persistence, and invasion. Virulence factors that are beneficial during early infection but are not advantageous during later stages can be rapidly turned on or off as required. Many *H. influenzae* virulence determinants are involved in adhesion to respiratory epithelial cells, inhibition of the host complement pathway, and subversion of the humoral immune response. The bacterium also possesses factors involved in nutrient acquisition that are required for virulence, and *H. influenzae* can form a biofilm in the respiratory tract and in the middle ear. Some of the major virulence factors of the bacterium are described below.

Polysaccharide Capsule

Encapsulated strains, or typeable *H. influenzae*, are separated into six capsular serotypes (a, b, c, d, e, and f). Each of these six capsule types is antigenically distinct, and thus no cross-protection against other serotypes of *H. influenzae* occurs in individuals vaccinated against Hib. The Hib capsule is composed of polyribosylribitol phosphate (PRP). Strains of Hib that have been genetically engineered to lack the PRP capsule do not cause invasive disease in animal models of infection. The capsule functions as a virulence factor by protecting the pathogen from complement deposition and subsequent complement-mediated lysis and phagocytosis. Hib strains expressing increased copy numbers of the Cap b locus, which is responsible for capsule production, exhibit increased serum resistance.

Antigenic Variation

During the course of infection, a successful pathogen adapts to evade the immune response or adjust to a new location within the host. This often involves the variation of cell surface antigens. Frequently, a surface protein or component provides a benefit for the pathogen in certain situations but may be detrimental when the pathogen disseminates to another location or the host immune response changes. To escape from the host immune response, pathogens have evolved mechanisms that allow for the expression of antigens to be turned on or off. When the genes encoding these antigens are rapidly turned on or off in a bacterial population at a high frequency and in a reversible manner, this process is referred to as phase variation. Phase variable genes in *H. influenzae* exhibit repeated nucleotide sequences that are prone to slip strand mispairing during replication. The result is insertions or deletions of base pairs into the gene, which can shift the open reading frame. Translation may be prematurely terminated and the gene product not expressed or transcription can be altered if the promoter region of the gene is affected. During infection, organisms that are expressing the most advantageous phase for a certain environment will be selected. In *H. influenzae*, many of the phase variable genes encode enzymes involved in lipooligosaccharide (LOS) biosynthesis. The role of phase variation in virulence is discussed in more detail in the sections below.

Lipooligosaccharide

Lipopolysaccharides (LPS) and LOS are major components of the outer membrane of Gram-negative bacteria. LPS and LOS differ in the length of the polysaccharide chain that extends from the lipid A inner core. LPS are characterized by the presence of the O antigen, a long region of repeating oligosaccharide units. O antigen accounts for the resistance of enterics to detergents and bile salts like deoxycholate. LOS have just one oligosaccharide unit and are sensitive to deoxycholate. LOS is produced by a subset of Gram-negative bacteria inhabiting airway mucosal surfaces that includes *Neisseria*, *Bordetella*, *Haemophilus*, and *Moraxella* spp. The LOS of *H. influenzae* is a major factor in virulence. This is especially true for NTHi. Because NTHi lack a polysaccharide capsule, the LOS is exposed to the harsh conditions that are encountered in the host and thus must provide the first line of defense against the innate immune response.

The inner core region of *H. influenzae* LOS is composed of lipid A, ketodeoxyoctanoate (KDO), and three conserved heptoses (Figure 1). The lipid A core of LOS is hexaacylated. Hexaacylation is critical for virulence. HtrB is an acyltransferase that performs one of the late acylation reactions in the biosynthesis of the lipid A core. NTHi and *H. influenzae* A2 insertional htrB mutants have the expected loss of lipid A acylation producing a mixture of pentaacyl and tetraacyl lipid A. Hib htrB mutants are attenuated for colonization and virulence in an infant rat colonization model. In human cells, htrB mutants elicit significantly less production of inflammatory cytokines from macrophages and airway cells and htrB mutants are unable to colonize human airway xenografts or immortalized human bronchial epithelial cells. In addition, htrB was identified as being transcriptionally upregulated during host cell colonization using a differential-display PCR strategy for the identification of *H. influenzae* genes upregulated during host cell infection. Immunochemical comparison of lipid A structures using a lipid A-specific monoclonal antibody has suggested that considerable heterogeneity exists among lipid A expressed by different *H. influenzae* strains. Moreover, studies have indicated that htrB itself is temporally expressed during host colonization and may be a determinant of the expression of other LOS biosynthetic genes.

Extending from the inner core heptose molecules are the highly variable oligosaccharides to which non-carbohydrate molecules can also be attached (Figure 1). This outer core region can be composed of glucose, galactose, N-acetylglucosamine, phosphorylcholine (ChoP) and/or sialic acid (Neu5Ac) but incorporation is dependent on expression of genes that are subject to phase variation. The result is often an LOS structure that mimics human glycosphingolipids including human blood group antigens. *Neisseria* and *Haemophilus* spp. can express a digalactoside (Gal-a 1, 4-Gal) that is contained within the human pK blood group antigen (Gal-a 1,4-Gal-8 1,4-Glc-ceramide), which humans do not make antibodies against. Addition of the digalactoside to the LOS is dependent on the phase-on expression of *lic2A* and *lgtC*, which are required for the addition of the proximal and distal galactose respectively. A recent study demonstrated that serum resistant *lic2A* and *lgtC* phase-on variants were selected for after serial passage of NTHi serum sensitive strains, and expression of both *lic2A* and *lgtC* was required for optimal serum resistance. Furthermore, expression of the digalactoside blocked IgG binding and subsequent complement-mediated killing. Thus, the digalactoside likely contributes to virulence directly through molecular mimicry of host proteins and indirectly by blocking antibody access to binding sites on the bacterium.

Other saccharide motifs in the outer core of LOS are also associated with virulence. The transferase LpsA is required for the addition of either a glucose or a galactose molecule onto the third heptose (HepIII) of the LOS. A threonine at position 151 of LpsA results in galactose attachment while a cysteine, alanine, or methionine results in the addition of glucose. If a glucose is attached, the resulting HepIII- β 1,2-glucose is a target for naturally acquired IgM, unless the epitope is shielded by extension of the oligosaccharide chain by Lic2A. NTHi strains that express the HepIII- β 1,2-glucose motif bind more IgM and are more susceptible to neutrophil-mediated killing. The predicted expression of the galactose or absence of saccharide on HepIII in invasive strains of NTHi was 3-fold more frequent than in carriage strains, suggesting that organisms without the HepIII- β 1,2-glucose may have a greater propensity to cause invasive disease because the bacteria are able to avoid recognition by host antibody. Serum resistance has also been associated with phase-on expression of *lex2A*. The expression of *lex2A* results in the substitution of glucose in the position where Lic2a would otherwise attach a galactose molecule. The outcome of phase-on expression of *lex2A* was similar to *lic2A* in that IgG binding is reduced.

Figure 1 Schematic representation of the structure of *H. influenzae* strain Rd lipooligosaccharide (LOS). Extension of the LOS is dependent on the expression of phase variable genes. Abbreviations: ChoP, phosphorylcholine; Neu5Ac, sialic acid; GalNac, acetylglucosamine; GA, galactose; GL, glucose; Hep, Heptose; PPEtn, pyrophosphoethanolamine; PEtn, phosphoethanolamine. KDO, ketodeoxyoctanoate.

The addition of sialic acid as a terminal structure upon the LOS is widely conserved among mucosal pathogens. *H. influenzae* isolates can sialylate terminal galactose structures on their LOS. The organism cannot synthesize sialic acid and must acquire it from the human host via a highly regulated and complex transport system (Figure 2). It also appears that *H. influenzae* can remove sialic acid from human glycoproteins. Once transported into the cell, sialic acid is activated by SiaB, enabling it to be used for sialylation. The addition of sialic acid to the LOS contributes to protection from complement-mediated killing initiated via the alternative pathway. It is unknown exactly how sialic acid prevents complement-mediated killing of NTHi although its role in virulence is clear. SiaB mutants that are unable to activate sialic acid are attenuated in the chinchilla otitis media model. These mutants are virulent in animal models when the complement has been depleted using cobra venom factor, confirming the role of sialic acid in the protection from complement-mediated killing. In *Neisseria gonorrhoeae*, sialylation blocks the alternative pathway of complement activation by binding factor H, a key pathway regulator. Sialylation has not been shown to affect the binding of factor H by NTHi.

Genomic analyses have identified three potential sialyltransferases in *H. influenzae* strains. One of these sialyltransferases, *lic3A*, is an α -2,3-sialyltransferase with homology to a sialyltransferase in *Campylobacter jejuni*. Colonization of the nasopharynx with Hib in an infant rat infection model leads to the selection of *lic3A* phase-on variants. Interestingly, pathogen populations in the blood and cerebrospinal fluid of rats that have been infected via intraperitoneal inoculation did not select for phase-on variants. In this infection model, the relative distribution of the variants was similar to the inoculum used in the study. This appears to indicate that the expression of *lic3A* may be more crucial to the colonization of the upper respiratory tract rather than more invasive infections. However, in a study that investigated phase variable gene expression in paired NTHi isolates from the nasopharynx and middle ear of children, it was found that *lic3A* phase-off was the preferred state in vivo for 15 of the 21 isolates, regardless of infection site. More studies in humans are necessary to determine if *lic3A* expression is required for initial colonization and to understand under what circumstances expression of *lic3A* is not favorable.

The LOS can be further modified with the addition of phosphorylcholine (ChoP). ChoP decoration of the cell surface is also shared by many mucosal pathogens, including Gram-positive pathogens like *S. pneumoniae*. Analyses of *H. influenzae* strains from patient samples or animal infection models have repeatedly demonstrated a significant enrichment for ChoP variants. ChoP binds to the platelet activating factor receptor (PAFR), functioning as an adhesin. Binding to PAFR stimulates a host cell signaling cascade that may function to initiate invasion. ChoP also provides protection against certain antimicrobial peptides and bactericidal IgM antibodies. However, a drawback of expressing ChoP on the cell surface is the activation of complement via the C-reactive protein, thus increasing susceptibility of the pathogen to complement-mediated killing. These opposing roles of ChoP are controlled in part by phase variation. Expression of ChoP requires the products of the *lic1* locus. This operon encodes for a choline kinase (*licA*), a choline transporter (*licB*), a pyrophosphorylase (*licC*), and a choline transferase (*licD*). Phase variation of ChoP expression is controlled by tandem tetrameric repeats found in the 5' end of *licA*. Infection models using Hib strains have demonstrated that *lic1* is predominately phase-on in colonization of the upper respiratory tract but this switches to a phase-off conformation at nonmucosal sites such as the blood and cerebrospinal fluid. NTHi strains expressing ChoP are better able to colonize the nasopharynx of chinchillas and promoted the development of otitis media. In a mouse infection model, ChoP expressing bacteria exhibited reduced antibody binding and greater outer membrane integrity, which was associated with increased bacterial survival. ChoP expressing variants were not selected for in SCID mice, demonstrating the requirement for selective pressures from the host adaptive immune response to induce phase variation. More recently, *licA* phase-on expression was found to significantly increase after experimental colonization of human volunteers. While only 3.8% of the inoculating NTHi population used in the study was phase-on, 18.8% of the population was phase-on three days after colonization and by day six there was an increase to 25.2%. These

Figure 2 A diagram describing the uptake of sialic acid by nontypeable *Haemophilus influenzae* (NTHi). NTHi cannot synthesize sialic acid and must acquire it from the human host. Sialic acid is released by an unknown mechanism from mucin, moves through the outer membrane porin, and is captured in the cytoplasmic space by a specific binding protein, SiaP, which delivers the sugar to a transporter, SiaT. SiaT is an ATP-independent TRAP transporter and the sialic acid is thought to move through it driven by proton motor force. Once in the cytoplasm, sialic acid can be either directed to the catabolic pathway as a nutrient or incorporated into the lipooligosaccharide and biofilm after conversion to the nucleotide sugar.

studies suggest that ChoP provides a protective benefit in a mucosal environment but expression must be turned off when the pathogen disseminates to nonmucosal sites. ChoP expression is also selected during biofilm growth in otitis media infections.

Pili

There are two types of pili found in strains of *H. influenzae*: hemagglutinating pili and type IV pili. The hemagglutinating pili are primarily found in Hib strains, although they appear to be present in a few NTHi strains (approximately 15% of strains). Expression of the pilus requires a five-gene operon (*hifABCDE*) that encodes for the structural proteins and proteins that assist in transport and assembly. Hemagglutinating pili promote adherence to respiratory epithelial cells and respiratory mucus, assisting in the colonization of the upper respiratory tract. The pili likely recognize sialylated lactosylceramide derivatives found in some human gangliosides. After initial colonization, the expression of pili is turned off by phase variation. Early studies of the hemagglutinating pili of Hib strains observed that isolates from the nasopharynx were predominately piliated, while isolates from more invasive sites did not express pili. These nonpiliated strains could readily revert to piliated upon *in vitro* passage and enrichment. This phase variation has also been observed in NTHi strains that express hemagglutinating pili, with nonpiliated organisms isolated from the middle ear. Phase variation of pili is controlled by stretch AT dinucleotide repeats that are found in the overlapping promoter region of *hifA* and *hifB*, which encode for the major structural subunit of the pilus and a chaperone required for assembly, respectively. Variation in the number of dinucleotide repeats alters the spacing between the –10 and –35 regions for both promoters, affecting transcription. Three conformations result in full expression (10 repeats), no expression (9 repeats), or intermediate expression (11 repeats). Often, isolates associated with more invasive disease such as meningitis are nonpiliated. Phase variation likely functions to prevent the effectiveness of a host antibody response. This is believed to be necessary to allow for the persistence and dissemination of the pathogen. Hemagglutinating pili are also antigenically diverse, especially those found in NTHi strains, thus reducing the utility as a vaccine component.

Type IV pili are primarily associated with NTHi strains. Type IV pili have been identified and characterized in *Pseudomonas aeruginosa*, *Vibrio cholerae*, *N. gonorrhoeae*, and other Gram-negative pathogens. As in other pathogens, NTHi type IV pili have been shown to be involved in biofilm formation, are required for twitching motility, and DNA uptake. Type IV pili found in NTHi biofilms likely contribute to the structural stability of the biofilm matrix and are also involved in adherence to human respiratory epithelial cells and the colonization of the respiratory tract of chinchillas. In NTHi, *PilA* is the type IV pilus that is expressed at highest levels. Genes in the *pilABCD* and *comABCDEF* are operons that control expression of type IV pili, and all gene products are necessary for optimal adherence to epithelial cells, biofilm formation, and competence.

Adhesins

In addition to pili, other adhesins are present in *H. influenzae* strains (Table 1). The first of the *H. influenzae* autotransporter adhesins to be described were HMW1 and HMW2. These proteins are found in approximately 45–75% of NTHi strains but are rarely present in encapsulated strains. Named for their high molecular weight (125 kDa for HMW1 and 120 kDa for HMW2), they were initially identified because they were able to elicit a strong antibody response during NTHi infections. They both share significant homology to the filamentous hemagglutinin of *Bordetella pertussis*. HMW1 and HMW2 are involved in *in vitro* adherence to various cell lines. The two adhesins promote adherence to different cell lines and thus are likely to recognize different receptors. Adherence is sensitive to the pretreatment of the host cells with proteinases, removal of oligosaccharides and sialic acid, and the incubation with lectins, indicating that the receptor is likely a sialylated glycoprotein. HMW1 has also been shown to be glycosylated.

As with hemagglutinating pili, phase variation of the adhesins HMW1 and HMW2 likely serves to prevent the host from mounting an effective antibody response. When chinchillas that had been immunized with either adhesin were infected with a strain expressing the corresponding protein, depressed expression of HMW was observed. This was found to be due to phase variation. As with hemagglutinating pili, phase variation is controlled by repeats found in the promoter region of structural gene. A 7 bp sequence is found with copy numbers ranging from 1 to 4 with decreasing mRNA and protein levels as the number of repeats increases. In a study that examined serial isolates of *H. influenzae* from individuals with COPD, the authors found that HMW1 and HMW2 expression decreased over time in most isolates, which correlated with increased numbers of 7 bp repeats and high serum levels of anti-HMW1/2 antibodies. Taken together, these studies suggest that the pathogen balances the benefits of expressing the adhesin early during infection by modulating expression of antigens once targeted by the humoral immune response.

The *H. influenzae* adhesin, or Hia, is found in 80% of NTHi strains that lack HMW1/HMW2. Hia shares significant homology with Hsf, an adhesin typically found in Hib and other encapsulated strains. Hia and Hsf are conserved at the N-terminal and C-terminal ends. Hsf is considerably larger than Hia (240 and 115 kDa, respectively). This difference is due to the presence of three copies of an internal protein domain in Hsf while Hia contains only one copy. Hia and Hsf are found to be flanked by the same open reading frames in their respective strains and thus appear to be in the same location on the genome. Hsf forms fibrils on the cell surface that are visible when negatively stained cells are viewed by transmission electron microscopy. These fibrils are not present on Hia-expressing strains. *Escherichia coli* strains expressing either Hia or Hsf exhibit similar adherence profiles to a panel of human cell lines, suggesting that the proteins bind to the same receptor, although the receptor has yet to be identified. Hsf was recently shown to bind to host vitronectin. Vitronectin is found both in the extracellular matrix (ECM) and in plasma and is an inhibitor of the host complement membrane attack complex. In addition to inhibiting complement, Hsf binding to vitronectin

Table 1 *H. influenzae* virulence factors involved in adhesion to respiratory epithelial cells

Virulence factor	Function	Phase variable expression
ChoP	Binds to PAFR on epithelial cells, involved in invasion, limits antibody and antimicrobial peptide binding, biofilm formation, activates complement	Yes; tetrameric repeats in <i>licA</i>
Hemagglutinating pili	Binding to epithelial cells and mucus	Yes; dinucleotide repeats in the <i>hifa</i> and <i>hifb</i> promoter
Type IV pili	Binding to epithelial cells, biofilm formation, twitching motility, competence	No
HMW(1,2)	Binding to epithelial cells	Yes; 7 bp repeats in <i>hmw</i> (1,2) promoter
Hia	Binding to epithelial cells	No
Hsf	Binding to epithelial cells and the ECM protein/complement inhibitor vitronectin	No
Hap	Binding to epithelial cells, bacterial aggregation and microcolony formation, binds the ECM proteins laminin and collagen IV and the ECM protein/complement inhibitor vitronectin	No
Protein E	Binding to epithelial cells, binds the ECM proteins vitronectin, laminin, and plasminogen, also binds hemin	No
Protein F	Binding to epithelial cells, binds the ECM protein laminin and the ECM protein/complement inhibitor vitronectin	No
P5	Binds to ICAM-1 and CEACAM-1 on epithelial cells and the complement inhibitor Factor H, limits IgM binding	No
Protein D	Binding to and invasion of epithelial cells and monocytes, increases expression of Chop, inhibition of cilia function	No

promotes bacterial adherence and invasion of respiratory epithelial cells, thus Hsf may mediate attachment via direct adhesion and through indirect interaction with vitronectin.

Similar to Hsf, many proteins involved in *H. influenzae* adhesion inhibit the host complement pathway and/or simultaneously bind to host ECM proteins, which often become exposed after damage to the lung epithelial cells from smoking or inflammation. Hap mediates adherence to host cells and also binds to the host ECM proteins fibronectin, laminin, and collagen IV. Hap has also been implicated in the promotion of bacterial aggregation and microcolony formation, an important early step in biofilm formation. The autoproteolysis of Hap is prevented by a leukocyte protease inhibitor that is produced by the host, preventing the release of the passenger domain from the cell surface. This mechanism allows the expression of Hap on the cell surface to be influenced by its local environment. Protein E is an outer membrane lipoprotein and Protein F is a membrane exposed ATP-binding cassette (ABC) transporter that are both involved in adherence of the organism to respiratory epithelial cells and both proteins bind to vitronectin and laminin. Protein E also binds plasminogen, which further enhances adhesion to the ECM and when the active plasmin protease is produced after host proteolytic processing of plasminogen, plasmin degrades the extracellular matrix proteins. Degradation possibly promotes dissemination of the bacterium. Plasmin bound to *H. influenzae* also degrades the complement component C3b. The adhesin P5 binds to ICAM-1 and CEACAM-1 on host epithelial cells and also binds the host inhibitor of the alternative complement pathway, Factor H. Additionally, P5 reduces IgM binding, thereby inhibiting activation of the classical complement pathway.

Protein D, the carrier protein in the new 10-valent pneumococcal vaccine is ubiquitously expressed in encapsulated *Haemophilus* and NTHi. The protein promotes adhesion to respiratory epithelial cells, but may do so indirectly by increasing ChoP decoration of the LOS. NTHi must obtain choline for ChoP biosynthesis from the host and Protein D has glycerophosphodiesterase activity that is thought to be involved in the cleavage of host choline-containing molecules. Protein D mutants exhibit both profound reductions in ChoP decoration of the LOS and adherence defects, thus it is likely that Protein D-mediated adherence is through ChoP binding to PAFR. However, adherence and internalization of NTHi by human monocytes is enhanced by Protein D and internalization is not associated with increased ChoP expression suggesting direct binding to this cell type. A role for Protein D in virulence has been demonstrated in both the rat and chinchilla models of otitis media.

IgA Protease

The immunoglobulin IgA1 is a significant component of the mucosal immune response. The *H. influenzae* protease genes *igaA* and *igaB* encode IgA1 proteases that neutralize these antibodies to aid in colonization and survival. Although IgA1 proteases appear to contribute to virulence, the proteases do not seem to be essential. IgA1 proteases are commonly found in *N. gonorrhoeae*, *Neisseria meningitidis*, *S. pneumoniae*, and other pathogens that colonize human mucosal surfaces but are usually absent in nonpathogenic *Haemophilus* species. Most strains of *H. influenzae*, both encapsulated and NTHi, possess at least one IgA1 protease; however, rare isolates that lack this proteolytic activity have been identified. In a human NTHi colonization study, there was a significant increase in the percentage of the NTHi population that was *igaB* phase-on after 6 days of nasopharyngeal colonization (12.5%) compared to the inoculating population (3.8%) suggesting that expression is beneficial during early colonization. A clonal group of strains expressing both *igaA* and *igaB* have been isolated from the respiratory tract of individuals with COPD, which raises the possibility that strains expressing both proteases are adapted for colonization of these hosts. *In vitro* studies have demonstrated that *igaA* promotes NTHi invasion of respiratory epithelial cells and *igaB* promotes intracellular persistence, but the mechanisms remain to be identified.

IgA1 protease is a secreted autotransporter protein. The N-terminal signal sequence of the 169 kDa precursor protein promotes transport to the periplasmic space. Next, the C-terminal outer membrane domain forms a 8-barrel in the outer membrane through which the internal passenger domain translocates to the cell surface. The serine protease activity of the protein then releases the protease domain from the surface, and an additional autoproteolytic event results in the mature protease. The IgA1 protease cleaves the hinge region of both the serum and the secreted forms of IgA1. Cleavage of the hinge region prevents the agglutinating activity of IgA1 by separating the antigen-binding Fab domains from the Fc portion of the antibody.

Acquisition of Iron, Zinc and Heme

Iron and heme acquisition are essential for survival during infection. In the host, iron is primarily stored intracellularly. Extracellular iron is sequestered in the serum by transferrin and in mucosal environments by lactoferrin, both of which are host iron-binding proteins. Pathogens have evolved mechanisms for releasing and acquiring iron from these sources. *H. influenzae* lack siderophores, the high-affinity iron chelators that are released by organisms into the environment, but an operon has been identified that may function in the capture and utilization of siderophores released by other organisms. *H. influenzae* utilize transferrin-binding proteins (Tbp1 and Tbp2) that are very similar to the transferrin-binding proteins of *Neisseria* species. In addition to Tbp1 and Tbp2, the cytoplasmic membrane protein TonB is required for the release of iron from transferrin. Tbp1, in complex with TonB, mediates the release of iron into the periplasm of the bacteria. Once in the periplasm, an ABC transporter moves the iron molecule across the cytoplasmic membrane. The ABC transporter consists of a periplasmic solute binding protein (FbpA), a permease protein (HitB), and an ATP-binding protein (HitC). FbpA binds the iron molecule and brings it to the HitB permease. The cleavage of ATP by HitC provides the energy necessary for the transport of the iron molecule into the cytoplasm.

Unable to synthesize heme, *H. influenzae* must also acquire it from the host. As with iron, heme is rarely found freely and is usually found bound to hemopexin and in hemoglobin/haptoglobin complexes. While some of the proteins involved in heme acquisition have been identified, a detailed model has not been elucidated. The HxuABC system is TonB-dependent and acquires heme from hemopexin. Other heme and hemoglobin binding proteins have been identified including HbpA, (heme-binding) and HgpA (hemoglobin binding). Transport via these receptors requires a lipoprotein that is encoded for by *hel*, which has a role in the transport of heme across the outer membrane. Transport of heme across the inner membrane requires Sap ABC transporters. The transporter permease SapBC and heme periplasmic binding protein SapA are required for transport into the cytoplasm. SapF is involved in heme utilization and was found to be important for biofilm formation, nasopharyngeal colonization, and acute otitis media in chinchillas. Recently, a study demonstrated that the adhesin Protein E binds hemin *in vitro*. The bound hemin could later be donated to *H. influenzae* that were starved of hemin, suggesting that Protein E may act as a storage reservoir for heme that can be released at times of limited availability.

Acquisition and regulation of zinc is critical for the survival and virulence of many organisms. Zinc is a cofactor for more than 300 enzymes in microorganisms and is reduced in host plasma during the acute phase response. Consequently, pathogens must be able to sufficiently obtain and utilize zinc during infection when host zinc is limited. Two zinc transporter systems have been identified in *H. influenzae*, ZnuABC and ZevAB. NTHi *zevA* and *zevB* mutants exhibit reduced ability to colonize lungs of mice.

Phasevarion

A regulatory system has been described for NTHi in which phase variation of the type III restriction– modification system controls multiple genes. The *modA* locus associated with this system encodes a DNA methyltransferase, that when expressed affects the methylation and subsequent expression of multiple phase variable genes. In *Haemophilus*, restriction activity has been lost or inactivated and it is certain that DNA restriction is not the function of the phase variable restriction-modification system. Rather, it is proposed that this system enables random switching of the organism between two different cell types with altered expression of virulence factors. Similar systems have been identified in *N. gonorrhoeae*, *N. meningitidis*, *Moraxella catarrhalis* and *Helicobacter pylori*.

Competence

H. influenzae is naturally competent and readily takes up extracellular DNA from the environment. *H. influenzae* can also acquire DNA that is carried within and coating the outside of vesicles that have been secreted by other *H. influenzae* bacteria and possibly other bacterial species. In NTHi, studies have shown that expression of the type IV pilus is required for DNA uptake. Once inside the cell, the DNA can be degraded and the nucleotides utilized for DNA replication or for metabolism. Alternatively, DNA may be incorporated into the genome through homologous recombination, which likely plays a considerable part in the genetic diversity of NTHi strains. However, competence may have initially evolved to function as a means for obtaining nucleotides for DNA synthesis rather than recombination. This viewpoint is supported by the fact that the regulation of competence is controlled by nutritional cues. The primary signaling molecule for competence induction is cyclic AMP (cAMP). cAMP is an intracellular signaling molecule produced by adenylate cyclase (CyaA). In *H. influenzae*, CyaA interacts with a phosphoenolpyruvate:fructose phosphotransferase

system (PTS), a transporter of fructose. When fructose is unavailable, CyaA produces cAMP, which is bound by the cAMP receptor protein (CRP). CRP is a global transcriptional regulator that regulates the expression of genes required for competence development as well as the acquisition and utilization of various carbon sources. Additional studies have determined that the availability of nucleic acid precursors also influences competence development. Competence can be induced by the addition of cAMP, upon entry into stationary phase growth, or by transferring cells to a defined starvation media. The latter approach is most commonly used in the genetic manipulation of *H. influenzae*. In combination with the publication of the complete genome sequence of *H. influenzae* KW-20 Rd, competence allows *H. influenzae* to be easily manipulated genetically, facilitating studies into virulence and cellular processes. The development of many genetic tools has greatly enhanced the capacity for advancements in *H. influenzae* research.

Colonization

H. influenzae has been found to have a high carrier rate in adults. When the human airway epithelium is compromised, *H. influenzae* can establish an infection. Nasopharyngeal colonization is the first step in pathogenesis. The bacterium must adhere to the respiratory epithelium and evade a number of host defenses including mucociliary clearance, secretory IgA, lysozyme, complement, lactoferrin, and antimicrobial peptides. Adherence of the bacterium to mucin may actually aid in clearance. Impairment of mucociliary clearance is a key step in the infective process. This can be achieved by a viral infection, cigarette smoke, cystic fibrosis, or a number of other causes. The bacterium can inhibit the function of cilia on nasopharyngeal cells by a Protein D dependent mechanism. Additionally, the LOS is toxic to ciliated epithelial cells and exacerbates impairment. With the mucociliary escalator impaired, the pathogen is now able to interact with nonciliated cells via one or more of its many adhesins. Next, the pathogen either invades the epithelial cell and passes to the subepithelial layer via transcytosis or aggregates and forms a biofilm.

It is unknown how *H. influenzae* establishes carriage, although invasion of respiratory epithelial cells, monocytes, and macrophages may be involved. While *H. influenzae* was not traditionally known as an intracellular pathogen, viable bacteria have been found within host cells suggesting that the organism invades host cells to escape the immune response. In one study, individuals with COPD exacerbations were found to have more intracellular NTHi than individuals with stable disease and no intracellular bacteria were found in healthy adults. The mechanisms leading to invasion are not completely understood. Invasion has been observed *in vitro* using cultured human epithelial cells and was found to be initiated by the binding of PAFR by ChoP on the LOS, but in a recent study, PAFR binding was found to be dispensable for respiratory epithelial invasion. It was found that NTHi invades by a mechanism that is dependent on host microtubule assembly, lipid rafts, and activation of phosphatidylinositol 3-kinase. Discrepancies in studies may originate from the differences in NTHi strains used and may indicate multiple mechanisms for adherence and invasion. NTHi IgaA and IgaB proteases participate in epithelial cell invasion and persistence respectively. The host β -glucan receptor has been implicated in adherence and invasion of *H. influenzae*, but further studies are needed to understand the pathogen-host interactions that mediate internalization. Macropinocytosis by bronchial epithelial cells also results in bacterial internalization. This mechanism involves extension of microvilli and the formation of lamellipodia, which engulfs the bacterium, and subsequent actin rearrangement.

In addition to intracellular invasion, *H. influenzae* are able to pass between cells to reach the subepithelial space. Translocation across the epithelium is enhanced after activation of a host transcriptional repressor of tight junction proteins by both *H. influenzae* and *S. pneumoniae* suggesting that both pathogens exploit the host immune response to gain access to the underlying tissue. Studies have found NTHi between the epithelial cells of bronchi and also in clusters in the submucosa. This phenomenon has also been observed in cultured cell lines. Often, cells can be observed in vacuoles of phagocytes in the epithelial layer. Currently, only one bacterial gene has been linked to promoting transcytosis, HI0638, which encodes for a putative lipoprotein of unknown function.

Modulation of the inflammatory response is an important aspect of colonization. Binding of the bacterium to epithelial cells can initiate inflammation through multiple pathways. The induction of cytokines promotes the recruitment of neutrophils, monocytes, eosinophils, and macrophages. The mucosal inflammatory response is primarily responsible for containment of the infection. Hosts in which inflammation is depressed are more likely to have invasive and recurrent infections. However, inflammation can be disadvantageous to the host, particularly in chronic lower respiratory tract infections and infections in cystic fibrosis patients. Increased inflammation damages epithelial cells, increases the production of mucus, prevents opsonophagocytosis, and recruits neutrophils, further impairing mucociliary clearance. Bacteria are then able to proliferate and disseminate.

Many bacteria, including *H. influenzae*, secrete outer membrane vesicles that have various effects on the immune response. *H. influenzae* secretes vesicles that contain LOS, DNA and proteins, many of which are associated with virulence. *H. influenzae* vesicles stimulate the production of antimicrobial peptides and IL-8 by respiratory epithelial cells, but whether secretions play a role in diverting the immune response away from bacterial cells has not been demonstrated.

Avoidance of complement and antibody are critical for *H. influenzae* persistence. Antibody-antigen complexes activate complement resulting in complement-mediated lysis of bacteria, and bound antibodies and complement promote phagocytosis of bacteria by host cells. Complement components are present in serum but have also been shown to be present at lower levels at the lung mucosal surfaces, especially during times of inflammation when the permeability of the mucosa increases. The polysaccharide of encapsulated strains provides a physical barrier that shields the bacterium from the effects of complement, sialylation and other LOS extensions inhibits complement activation, and many adhesins bind to host inhibitors of the complement system to exploit the inhibitors for their own protection. Multiple *H. influenzae* adhesins bind the host complement inhibitors vitronectin and Factor

H and the bacterium can also bind to the inhibitor C4BP although the binding partner has not been identified. The importance of complement in the host response is evidenced by individuals with C2 and C3 deficiencies whom are at increased risk of *Haemophilus* infection.

The bacterium utilizes multiple strategies to escape recognition by antibodies which include production of proteases that cleave IgA1, modification of the LOS to block antibodies from reaching their target, molecular mimicry of host antigens, antigenic variation of surface proteins, and intracellular invasion of host cells. Modification of the *H. influenzae* cell membrane has also been shown to reduce antibody binding. The NTHi transporters VacJ and Yrb inhibit IgM binding through removal of phospholipids from the outer membrane, which results in increased density of the oligosaccharides in the LOS and reduced access to IgM epitopes. Furthermore, transcription of both VacJ and Yrb was found to be increased in serum resistant clinical strains. Limiting IgM binding is likely critical for invasion of the bacterium from the upper respiratory to the lower respiratory tract. NTHi isolates recovered from the lower respiratory tract of patients with COPD bind less IgM and are more resistant to serum than isolates recovered from the upper respiratory tract. *H. influenzae* may also subvert the host humoral response through polyclonal activation of B cells. *H. influenzae* vesicles bind to the IgD receptor of B cells, which results in polyclonal activation and antibody secretion that is not specific to the bacterium. Similarly, NTHi has been shown to activate tonsillar B cells in a polyclonal manner. In a recent study, NTHi was isolated from 51% of tonsils from children undergoing tonsillectomy, where it was identified as the predominant bacterial species associated with tonsillar hypertrophy and was found to reside intracellularly. NTHi activated and was internalized by the tonsillar B cells in an IgD receptor-dependent manner, but the antibody produced by the B cells was not directed towards NTHi. Polyclonal B cell activation could be a mechanism utilized by NTHi to delay the development of an appropriate humoral response to *H. influenzae*. The host humoral response is critical in limiting disease. Individuals with primary antibody deficiencies have multiple exacerbations of NTHi disease over time with some strains persisting for up to 43 months after colonization.

Biofilm Formation

A biofilm is defined as a community of surface-associated bacteria that are usually surrounded by an exopolysaccharide matrix. Bacteria in a biofilm are more resistant to antimicrobial peptides and antibiotics than free-living planktonic bacteria. The matrix of the biofilm also plays a role in the protection from the host innate immune response. Pathogens can decorate components of the matrix to mask the biofilm and present it as 'self' to the host. Biofilms contribute to persistent and recurring infections. The protective properties of the biofilm make it difficult for the immune response to clear the pathogen and present a challenge in the treatment of biofilm-associated infections. There are several well-defined steps to biofilm formation (**Figure 3**). First, a bacterium adheres to a surface. Additional adhesins then interact with receptors and the bacterial cell forms a more intimate association. Additional cells are recruited and a microcolony is formed. The bacteria begin the production of the biofilm matrix and the biofilm continues to grow. Mature biofilms will have defined water channels that allow for the flow of nutrients and the release of waste throughout the biofilm. Conditions in the biofilm can vary significantly, depending on the ultrastructure. For example, oxygen levels will be higher closer to the surface of the biofilm while conditions are more anaerobic in the interior environment. It is possible that these types of changes impact the effectiveness of antibiotics. **Figure 4** shows a scanning electron microscopic image of an *H. influenzae* biofilm over airway epithelial cells.

The involvement of biofilm formation in NTHi infections has been well established, particularly in otitis media. Some patients presenting with chronic otitis media will produce sterile effusions, leading to the conclusion that the infection is not a bacterial infection but a sterile inflammatory process. However, bacterial DNA and mRNA can be detected in these effusions indicating that a bacterial pathogen is responsible. The failure to culture bacteria from the effusion is likely due to the bacteria to be associated to a biofilm, rather than free-living. It appears that antibiotic treatment contributes to the absence of bacteria in effusions, but other causes or mechanisms cannot be dismissed. The chinchilla model of otitis media has been used to demonstrate the role of NTHi biofilms in sterile infusions. More recently, bacterial biofilms were observed in middle ear mucosa biopsy specimens from children that were being treated for recurring otitis media infections.

In addition to middle ear infections, there is evidence that NTHi strains may form biofilms in the upper respiratory tract. Evidence of bacterial biofilms can be observed in bronchoalveolar lavage of cystic fibrosis patients. A study of patients with chronic rhinosinusitis confirmed the presence of bacterial biofilms on the sinus mucosa. *H. influenzae* was the predominant bacterial species in these biofilms. Interestingly, bacterial biofilms are also observed on healthy control samples suggesting that biofilm formation may be beneficial to the host in some circumstances.

Biofilm formation by *H. influenzae* appears to primarily be a function of unencapsulated NTHi strains. In one study, Hib strains were found to produce small amounts of biofilms *in vitro*, but production was reduced compared to NTHi strains and encapsulated strains have not been demonstrated to produce biofilms *in vivo*. Capsule may prevent the tight association required for the bacterial cell to adhere to a surface and interact with other bacteria.

A number of factors are involved in biofilm formation by NTHi. Many of the protein adhesins discussed above are also found in the extracellular matrix of the biofilm. Antibodies to Hap and HMW proteins have been used to detect these proteins in the matrix. However, since Hap and HMW are cell surface proteins, it is not surprising to find them associated with biofilms. Hap has been demonstrated to mediate microcolony formation by promoting aggregation, thus contributing to the early stages of biofilm formation. Strains lacking the type IV pili exhibit impaired biofilm formation *in vitro*. Type IV pili likely contribute to the

Figure 3 Steps in biofilm formation. The arrows designate production of quorum sensing molecules by the bacterium that triggers a coordinated response within the biofilm. Steps A, B, and C represent the early stages in microcolony formation on the biological surface followed by formation of the biofilm and the accompanying matrix. Bacteria are continually shed from the biofilm as planktonic cells, which can then establish new biofilms.

Figure 4 Nontypeable *Haemophilus influenzae* forming a biofilm over human airway epithelial cells in culture. Organisms covered with matrix can be readily seen.

maintenance of the biofilm structure. In addition to proteins, DNA may also provide structural stability to NTHi biofilms. In a detailed microscopy study of *in vivo* biofilms, it was observed that DNA forms a dense network of strands and dense rope-like structures.

Carbohydrate structures also play a key role in the biofilm structure. The precise nature of the NTHi exo- polymeric matrix is unknown, but certain features have been defined. Sialic acid is found to be a terminal non- reducing sugar of matrix glycoconjugants. An NTHi strain that expresses a truncated LOS lacking the acceptor for sialic acid, can still produce a biofilm that contains sialic acid. This indicates that sialic acid is used to decorate the biofilm matrix, which likely provides protection from the innate immune response of the host. Inactivation of various sialyltransferases or the CMP-Neu5Ac synthetase results in defective biofilm formation in a chinchilla infection model. WecA is an enzyme involved in the synthesis of the sialylated structure of the biofilm matrix. Inactivation of WecA results in the inability to form a biofilm *in vivo*.

ChoP also contributes to the persistence of NTHi biofilms. ChoP is found on the LOS and its expression is phase variable, as discussed above. Despite the increased susceptibility of ChoP expressing strains to complement- mediated killing, these strains are predominant in animal infection models, indicating that ChoP provides a beneficial function to the pathogen. In biofilm formation, the ChoP content of the LOS is elevated and this LOS is less inflammatory. A strain that is unable to express ChoP provokes an increased early inflammatory response and is unable to establish a robust biofilm in a chinchilla model for otitis media. Clearly, expression of ChoP on the LOS allows for the establishment of a biofilm, contributes to persistence, and illustrates how NTHi evade the host immune response.

Bacterial quorum sensing promotes formation and remodeling of bacterial biofilms. Quorum sensing involves the release of small molecule autoinducers by bacteria within biofilms in response to density. In NTHi, quorum sensing enhances biofilm formation, but it is not required. Production of the AI-2 autoinducer, a furanosyl borate diester, is dependent on *luxS*. NTHi *luxS* mutants can form biofilms but the thickness and density are decreased. Studies in the chinchilla otitis media model revealed that survival of *luxS* NTHi mutants is reduced, but decreased ChoP expression in the *luxS* mutant may contribute to the decrease in virulence. Mutation of *rbsB*, the gene encoding the NTHi periplasmic receptor for AI-2, results in decreased uptake of AI-2 by NTHi

and also results in reduced biofilm formation. Additionally, the QseB/QseC two-component system is involved in biofilm formation, but in an AI-2 independent manner.

Bacteria in biofilms are known to be more resistant to antibiotics, but in recent studies, antibiotics have been found to enhance biofilm production for a number of bacterial species as a result of altered gene expression. Similarly, sub-inhibitory concentrations of the β -lactam antibiotics amoxicillin, ampicillin, and cefuroxime were found to modulate gene expression and induce NTHi biofilm formation. Antibiotic treatment with suboptimal dosages of β -lactams resulted in biofilms with increased density and biomass *in vitro*. Prior antibiotic exposure also increased resistance to a lethal dose of cefuroxime.

NTHi and *S. pneumoniae* are found together within middle ear biofilms of children with chronic otitis media. However, only a few studies have investigated how polymicrobial biofilm formation contributes to pathogenesis. In the chinchilla otitis media model, mixed infection with NTHi and *S. pneumoniae* results in larger middle ear biofilms compared to infection with either species alone. Increased biofilm formation was associated with reduced systemic spread of *S. pneumoniae*, suggesting that mixed infection could be of some benefit to the host. Co-infection may also be advantageous to both bacterial species. In another study in chinchillas, co-infection was associated with the enhanced recovery of NTHi compared to mono-NTHi infection. In addition, co-infection with either a β -lactamase producing or a non-producing strain of NTHi resulted in reduced amoxicillin-mediated killing of *S. pneumoniae* within biofilms, although only the β -lactamase producing NTHi strain was capable of reducing killing of planktonic *S. pneumoniae*. This study suggests that NTHi promotes *S. pneumoniae* resistance to amoxicillin directly through β -lactamase production and passively through enhanced biofilm formation and that *S. pneumoniae* provides reciprocal protection to NTHi. More studies examining the genetic modulation of bacteria within mixed biofilms and the effects of the resident microbiota on biofilm formation are necessary to better understand the impact of multispecies biofilms in the host.

Conclusion

H. influenzae is a strict human pathogen that utilizes multiple virulence factors to persist in the host. While some host factors that predispose to the development of disease have been identified, disease can also develop in healthy individuals. Further studies are needed to understand the complex interactions that occur between *H. influenzae*, the microbial flora, and the host.

Halophilic Archaea

Aharon Oren, The Hebrew University of Jerusalem, Jerusalem, Israel

© 2019 Elsevier Inc. All rights reserved.

Glossary

Alkaliphiles Microorganisms that require high pH for growth.

Archaeol Core lipid consisting of two phytanyl (C20) chains bound to glycerol by ether bonds.

Bacteriorhodopsin A membrane-bound protein containing a retinal moiety, serving as a light-driven proton pump.

Compatible solutes Small organic molecules accumulated inside the cell to provide osmotic balance.

Glycolipids Lipids that contain bound sugar moieties.

Haloalkaliphiles Microorganisms that require both high salt concentrations and high pH for growth.

Halorhodopsin A membrane-bound protein containing a retinal moiety, serving as a light-driven chloride pump.

Methanogens Anaerobic archaea that produce methane.

Nanohaloarchaea A group of very small (~0.6 µm) Euryarchaeota living in hypersaline waters, only remotely related to the Halobacteria class.

Defining Statement

The halophilic archaea of the class *Halobacteria* (phylum *Euryarchaeota*) form a large and metabolically diverse group of prokaryotes that strictly depend on the presence of high salt concentrations much above that of seawater, and many can grow in salt-saturated brines. They are found in salt lakes and other hypersaline environments worldwide. Halophiles are also found in two other lineages of *Euryarchaeota*: the methanogenic *Methanosarcinaceae* family and the 'Nanohaloarchaea', a group of which no representatives have yet been cultivated.

Introduction

When in the late 1970s Carl Woese first used 16S rRNA sequence information to deduce the phylogenetic relationships between different groups of prokaryotes, it was quickly realized that the group of generally red-pigmented aerobic extremely halophilic prokaryotes classified in the family *Halobacteriaceae* belong to the newly defined group of the Archaeobacteria, now named Archaea, together with the methanogens and certain hyperthermophilic and thermoacidophilic prokaryotes. This result was first described in a paper published in 1978 entitled 'Are extreme halophiles actually bacteria?', based on a study of the small subunit ribosomal RNA of *Halobacterium halobium* and *Halobacterium cutirubrum*, isolates later reclassified as strains of *Halobacterium salinarum*.

Indeed, hypersaline environments worldwide with salt concentrations up to saturation are inhabited by halophilic Archaea of the *Halobacteria* class, and these pigmented microorganisms are often present in sufficiently high densities to color the waters of salt lakes red. An example of such pink-red brines in a crystallizer pond of a solar saltern is shown in Fig. 1. The pigmented Archaea generally coexist with other groups of microorganisms adapted to life at high salt concentrations. These include a few types of Bacteria and unicellular eukaryotic algae of the genus *Dunaliella*. Most members of the *Halobacteria* live by aerobic respiration, but some a few representatives of the group prefer an anaerobic life style.

Among the methanogenic Archaea a few species are adapted to life at high salt concentrations. Most of these belong to the family *Methanosarcinaceae*. Some members of the *Halobacteria* also prefer an anaerobic life style. Cultivation-independent metagenomic studies of the biota of hypersaline environments have recently led to the discovery of a third group of halophilic Archaea: the 'Nanohaloarchaea'. These organisms are characterized by very small cells. All halophilic Archaea known thus far belong to the Euryarchaeota phylum. No representatives of the Crenarchaeota have yet been discovered in high-salt environments.

Most of this article deals with the biology of the *Halobacteria*. The halophilic methanogens and the 'Nanohaloarchaea' are discussed in the last sections of this article.

The Halobacteria

Taxonomy

The class *Halobacteria*, affiliated with the archaeal phylum *Euryarchaeota*, currently (May 2018) encompasses 3 orders and 6 families with a total of 59 genera and 246 species (Table 1). The class was circumscribed on the basis of small subunit rRNA gene sequence similarity, the high salt requirement of its members, and their physiological and chemotaxonomic features.

Fig. 1 A saltern crystallizer pond near Eilat, Israel, colored pink by halophilic Archaea (*Haloquadratum* and others). Unicellular algae (*Dunaliella salina*) and pigmented Bacteria (*Salinibacter*) also may contribute to the color of the brine. Photograph by the author.

Until 2015 the members of the *Halobacteria* were classified in a single order, the *Halobacteriales* and a single family, the *Halobacteriaceae*. The nomenclatural type is the genus *Halobacterium* with type species *Halobacterium salinarum*. Based on a comparative analysis of 129 sequenced genomes to identify shared molecular characteristics, including conserved signature insertions/deletions and conserved signature proteins, improved phylogenetic trees were constructed that provide a better understanding of the relationships between the organisms than can be deduced from 16S rRNA gene-based trees. This led to the splitting of the class into three orders, the *Halobacteriales* and two new orders: the *Natrialbales* and the *Haloferacales*, and a total of six families: the *Halobacteriaceae*, the *Haloarculaceae*, the *Halococcaceae* (order *Halobacteriales*), the *Haloferacaceae* and the *Halorubraceae* (order *Haloferacales*), and the *Natrialbaceae* (order *Natrialbales*). Haloalkaliphilic species that require high pH values (9–10 and higher) in addition to the requirement for high salt concentrations are found mainly in the orders *Natrialbales* and *Halobacteriales*; only few members of the *Haloferacales* are adapted to life at high salt and high pH. The order *Halobacteriales* contains a few representatives that are moderate acidophiles, preferring life at pH ~4.5, as well as a few species that prefer an anaerobic life style.

The chromosomes are between 2.0 and 4.5 Mb in length. Many species of *Halobacteriaceae* contain, in addition to the main chromosome, additional DNA in 'minichromosomes', 'megaplasmids' or plasmids. An extreme case is *Haloarcula marismortui* with nine circular replicons: two 'chromosomes' (3.1 and 0.28 Mb) and 7 plasmids. In some species 25%–30% of the genetic material is found outside the main chromosome. The number of rRNA operons encoded by these genomes varies between 1 and 3. Especially in the genera *Haloarcula* and *Halomicrobium* the multiple 16S rRNA genes can differ greatly in nucleotide sequence. Thus, the *rnaA* and *rnaB* genes of *Haloarcula marismortui* show substitutions in 74 positions, i.e., ~5% sequence difference. Both genes can be expressed so that each individual cell may contain ribosomes with either types of 16S rRNA.

The genome of *Haloquadratum walsbyi*, an unusually shaped flat square archaeon (Fig. 2), is of special interest: it has the lowest G+C content of all members of the class (47.9 mol%), and coding density is low: 76%, as compared to 86%–91% in other haloarchaea, a phenomenon caused by a very large average intergenic spacing and more than a thousand intergenic regions. It also encodes the largest protein identified in the group: the 9159 amino acids long halomucin, a protein associated with the cell envelope.

Chemotaxonomy and Physiology

The cells of most members of the *Halobacteria* lyse when suspended at salt concentrations below 100–150 g l⁻¹. Thus, high salinities are required not only for growth, but also for the maintenance of structural stability and integrity. With the exception of a few coccus-shaped genera (*Halococcus*, *Natronococcus*), the cell shape is maintained by an S-layer cell wall composed of a high molecular weight glycoprotein. The cell wall glycoprotein of *Halobacterium salinarum* (molecular mass ~120 kDa) consists of an 87-kDa core protein rich in acidic amino acids with attached acidic and neutral saccharide chains. The primary structure of the protein backbone and the mode of glycosylation vary among the species. Similar to most other proteins encoded by the genomes of the *Halobacteria*, the acidic cell wall protein denatures at low salt. As a result, suspension of the cells in fresh water leads to dissolution of the cell wall.

In contrast, members of the genus *Halococcus* (the single genus in the family *Halococcaceae*) possess a thick sulfated heteropolysaccharide cell wall that is not damaged in the absence of salt. The alkaliphilic coccoid genus *Natronococcus* (family *Natrialbaceae*) has a rigid cell wall of a different composition: it is built of repeating units of a poly(L-glutamine) glycoconjugate. Also these cells do not lyse when suspended in low salt solutions.

Table 1 The orders, families and genera of halophilic Archaea in the phylum *Euryarchaeota* with validly published names (as of May 2018)

Order	Family	Genus	Number of species	Type species	Comments
<i>Halobacteriales</i>	<i>Halobacteriaceae</i>	<i>Haladaptatus</i>	4	<i>Hap. paucihalophilus</i>	Cells remain viable for prolonged times at low salt concentrations
		<i>Halalkalicoccus</i>	3	<i>Hac. tibetensis</i>	Some species are haloalkaliphilic
		<i>Halanaeroarchaeum</i>	1	<i>Haa. sulfurireducens</i>	Anaerobic, oxidizing acetate with elemental sulfur as the electron acceptor
		<i>Halarchaeum</i>	6	<i>Hla. acidiphilum</i>	Some species are slightly acidophilic
		<i>Haloarchaeobius</i>	5	<i>Hab. iranensis</i>	
		<i>Halobacterium</i>	5	<i>Hbt. salinarum</i>	Type genus of the family
		<i>Halocalculus</i>	1	<i>Hcl. aciditolerans</i>	Slightly acidophilic
		<i>Halodesulfurarchaeum</i>	1	<i>Hda. formicium</i>	Anaerobic, oxidizing formate or hydrogen with elemental sulfur or thiosulfate as the electron acceptor
		<i>Halomarina</i>	3	<i>Hmr. oriensis</i>	
		<i>Halorubellus</i>	3	<i>Hrb. litoreus</i>	
		<i>Halorussus</i>	4	<i>Hrs. rarus</i>	
		<i>Halostella</i>	1	<i>Hsl. salina</i>	
		<i>Halovenus</i>	3	<i>Hvn. aranensis</i>	
		<i>Natronoarchaeum</i>	4	<i>Nac. mannaniyticum</i>	One species is moderately alkaliphilic
		<i>Salarchaeum</i>	1	<i>Sar. laminariae</i>	
		<i>Salinirubrum</i>	1	<i>Srr. litoreum</i>	
	<i>Haloarculaceae</i>	<i>Halapricum</i>	1	<i>Hpr. salinum</i>	
		<i>Haloarcula</i>	9	<i>Har. vallismortis</i>	Type genus of the family
		<i>Halomicroarcula</i>	3	<i>Hma. pellucida</i>	
		<i>Halomicrobium</i>	3	<i>Hmc. mukohataei</i>	
		<i>Halorhabdus</i>	2	<i>Hrd. utahensis</i>	One species preferentially grows anaerobically by fermentation and is not pigmented
		<i>Halorientalis</i>	3	<i>Hos. regularis</i>	
		<i>Halosiccatus</i>	1	<i>Hsc. urmianus</i>	
		<i>Halosimplex</i>	4	<i>Hsx. carlsbergense</i>	
		<i>Natronomonas</i>	3	<i>Nmn. pharaonis</i>	Haloalkaliphilic
		<i>Salinirubellus</i>	1	<i>Srb. salinus</i>	
	<i>Halococcaceae</i>	<i>Halococcus</i>	9	<i>Hcc. morrhuae</i>	Type genus of the family. Cocci that do not lyse in distilled water
<i>Haloferacales</i>	<i>Haloferacaceae</i>	<i>Halobellus</i>	8	<i>Hbs. clavatus</i>	
		<i>Haloferax</i>	13	<i>Hfx. volcanii</i>	Type genus of the family
		<i>Halogeometricum</i>	4	<i>Hgm. borinquense</i>	
		<i>Halogramum</i>	4	<i>Hgn. rubrum</i>	
		<i>Halopelagius</i>	3	<i>Hpl. inordinatus</i>	
		<i>Haloplanus</i>	7	<i>Hpn. natans</i>	
		<i>Haloprofundus</i>	1	<i>Hpd. marisrubri</i>	Isolated from a deep-sea brine
		<i>Haloquadratum</i>	1	<i>Hqr. walsbyi</i>	Flat square to rectangular cells
	<i>Halorubraceae</i>	<i>Halobaculum</i>	3	<i>Hbl. gomorreense</i>	
		<i>Halobium</i>	2	<i>Hbm. palmae</i>	
		<i>Halohasta</i>	2	<i>Hht. litorea</i>	
		<i>Halolamina</i>	6	<i>Hlm. pelagica</i>	
		<i>Halonotius</i>	1	<i>Hns. pteroides</i>	
		<i>Haloparvum</i>	2	<i>Hpv. sedimenti</i>	
		<i>Halopenitus</i>	3	<i>Hpt. persicus</i>	
		<i>Halorubrum</i>	37	<i>Hrr. saccharovororum</i>	Type genus of the family; also contains a few haloalkaliphilic species
		<i>Salinigranum</i>	2	<i>Sgn. rubrum</i>	
<i>Natrialbales</i>	<i>Natrialbaceae</i>	<i>Halobiforma</i>	3	<i>Hbf. haloterrestis</i>	Some species are haloalkaliphilic
		<i>Halopiger</i>	6	<i>Hpg. xanaduensis</i>	
		<i>Halostagnicola</i>	4	<i>Hst. larsenii</i>	Some species are haloalkaliphilic

Methanosarcinales	<i>Methanosarcinaceae</i>				The family also contains non-halophiles
		<i>Methanohalobium</i>	1	<i>M. evestigatum</i>	
		<i>Methanohalophilus</i>	4	<i>M. mahii</i>	
		<i>Methanosalsum</i>	2	<i>M. zhilinae</i>	

Fig. 2 Square and rectangular halophilic archaea (*Haloquadratum walsbyi*) in the brine of a saltern crystallizer pond near Eilat, Israel. Phase-contrast; bar=10 μ m. Cells were concentrated by centrifugation, causing collapse of the gas vesicles. Photograph by the author.

The polar lipids of the *Halobacteria* are based on branched 20-carbon (phytanyl) and in some genera also 25-carbon (sesterterpanyl) chains, bound by ether bonds to glycerol. Fig. 3 shows the diether core lipids that forms the basis for most of the polar lipid structures: 2,3-di-O-phytanyl-*sn*-glycerol ($C_{20}C_{20}$) (archaeol) and 2-O-sesterterpanyl-3-O-phytanyl-*sn*-glycerol ($C_{25}C_{20}$). The hydrophobic chains are generally fully saturated, but unsaturated phytanyl ('phytenyl') chains were documented in *Halorubrum lacusprofundi*, a facultative psychrophilic species isolated from Deep Lake, Antarctica, that can to grow at temperatures down to 4°C.

Substitution of the free hydroxyl groups on the glycerol moiety enables the formation of a variety of polar lipids, including phospholipids, sulfolipids, and glycolipids. The types of polar lipids present differ among the genera of *Halobacteria*. All genera contain the diphytanyl diether derivatives of phosphatidylglycerol and the methyl derivative of phosphatidylglycerol phosphate. Phosphatidylglycerol sulfate is found in many genera. The alkaliphilic *Natronococcus occultus* has an unusual phospholipid with a cyclic phosphate group. Glycolipids are found in the neutrophilic species, but they are generally absent in the alkaliphilic members. Neutrophilic species may possess a variety of glycolipids with two, three or four sugar moieties, some of which may carry one or more sulfate groups. Not all glycolipids of the *Halobacteria* have yet been fully characterized.

Fig. 3 The core lipids of halophilic archaea of the class *Halobacteria*: (A) 2,3-di-*O*-phytanyl-*sn*-glycerol ($C_{20}C_{20}$) and (B) 2-*O*-sesterterpanyl-3-*O*-phytanyl-*sn*-glycerol ($C_{20}C_{25}$) (not present in all genera). The free hydroxy group can bind different substituents to form phospholipids, glycolipids and sulfolipids.

The pink-red color of the cells of most species of *Halobacteria*, as shown in Fig. 1, is mainly caused by the presence of carotenoid pigments in their cell membrane. Only a few species are devoid of pigments. One example is *Natrialba asiatica* ('alba' in Latin means 'white'), isolated from beach sand in Japan. Species with an anaerobic life style such as *Halorhabdus tiamatea* isolated from a deep-sea brine on the bottom of the Red Sea and the obligate anaerobe *Halanaeroarchaeum sulfurireducens* isolated from hypersaline lakes in Altai, Russia, are not pigmented. Some *Haloferax* species are pigmented when grown at relatively low salinity ($\sim 150 \text{ g l}^{-1} \text{ NaCl}$) but can be almost colorless when grown at higher salt concentrations (250 g l^{-1}). The dominant carotenoids in the cell membrane of *Halobacteria* are generally the open-chain 50-carbon compounds α -bacterioruberin and different derivatives such as monoanhydrobacterioruberin and bis-anhydrobacterioruberin. C_{40} carotenoids such as lycopene and β -carotene are sometimes present in small amounts. The primary function of the carotenoid pigments appears to be to protect the cells against oxidative damage at high light intensities. Thus, it was shown that at high light intensities pigmented cells of *Halobacterium salinarum* out-competed a carotenoid-less mutant. The bacterioruberin pigments may also have additional functions such as the stabilization of the cell membrane structure.

An additional source of pigmentation of many members of the class *Halobacteria* can be the presence of retinal-containing proteins in their membranes. The best known retinal protein that can contribute a purple color to the cells is bacteriorhodopsin. It is a 27-kDa protein with seven trans-membrane helices and carrying retinal (a 20-carbon carotenoid derivative) as a prosthetic group. Bacteriorhodopsin serves as a light-driven proton pump. Upon excitation (maximum light absorbance at 570 nm) the molecule undergoes a complex photocycle during which also the stereochemistry of the retinal moiety changes as one of the double bonds changes from the *trans* to the *cis* conformation, and the Schiff base that binds the retinal to a lysine residue of the protein is deprotonated and protonated. As a result of these light-driven events a proton is transported from the inside of the cell to the outer medium. Thus, a proton gradient is established that can be used for the generation of ATP or for other energy-requiring processes. Light can supply the energy needed to drive anaerobic growth in *Halobacterium salinarum* cells that contain bacteriorhodopsin. However, photoautotrophic growth was never yet shown in this group: autotrophic CO_2 fixation is not possible, so that the cells depend on organic carbon sources. In *Hbt. salinarum* bacteriorhodopsin occurs in specialized patches of the cell membrane ('purple membrane'). Expression of the protein is induced by low oxygen tension and by light. Not all members of the *Halobacteria* possess the genes for the formation of bacteriorhodopsin and other retinal proteins.

Many members of the group have a second retinal protein, halorhodopsin. Its structure is similar to that of bacteriorhodopsin, but it acts as a light-driven chloride pump, transporting chloride from the outside medium to the cytoplasm. Inward chloride transport is important to maintain the proper ionic balance, and is essential for cell growth.

Motility by means of flagella is found in many species of *Halobacteria*, and such motile cells often show phototaxis so that cells can position themselves at optional light intensities and optimal light spectral quality for the operation of the light-driven retinal-containing pumps. Additional types of retinal proteins can serve as light sensors. Thus, *Hbt. salinarum* contains two sensory rhodopsins. Sensory rhodopsin I is a receptor for green light to which the cells are attracted, sensory rhodopsin II, also named phoborhodopsin, is a receptor for blue light that acts as a repellent. *Haloquadratum walsbyi*, which does not have flagella and therefore cannot be phototactic, has bacteriorhodopsin and halorhodopsin, but lacks sensory rhodopsins.

Some members of the *Halobacteria*, including *Halobacterium salinarum*, *Haloferax mediterranei*, *Haloquadratum walsbyi*, *Halogeometricum borinquense*, and *Halorubrum vacuolatum*, produce intracellular gas vesicles. Gas vesicles are made by some other groups of prokaryotes as well, including many cyanobacteria and some members of the *Proteobacteria*. Thus, this property is not a unique feature of the halophilic Archaea. The presence of gas vesicles decreases the density of the cells and increases buoyancy. This can be favorable when it enables the cells to float to the surface of the brine where the availability of light (as energy source, mediated by the bacteriorhodopsin proton pump) and oxygen for respiration may be increased. However, there is little evidence to show that in their natural environments cells indeed float to the brine surface thanks to their ability to produce gas vesicles.

Microorganisms that live at high salt concentrations need to keep their cytoplasm at least isosmotic with their environment. As biological membranes are permeable to water, maintenance of a dilute cytoplasm is not possible as the cell would rapidly dry out. Therefore all halophilic and halotolerant microorganisms need to adjust the osmotic pressure of their cytoplasm to that of the saline or hypersaline medium in which they live. This can be achieved in different ways. One strategy is the accumulation of inorganic ions for osmotic balance. This 'salt-in' strategy was adopted by a few specialized groups of halophiles only: the Archaea of the class *Halobacteria*, some aerobic Bacteria belonging to the *Bacteroidetes* (genus *Salinibacter* and relatives), and anaerobic halophiles affiliated with the *Firmicutes* (order *Halanaerobiales*). Such microorganisms contain intracellular chloride concentrations comparable to those of their medium, but sodium ions are excluded from the cells as much as possible. Cells that use the 'salt-in' strategy instead contain high concentrations of potassium ions.

An alternative way to achieve osmotic adaptation is by the synthesis (or accumulation from the medium, if available) of small organic, generally uncharged or zwitterionic compounds. Most halophilic and halotolerant microorganisms use such organic osmotic solutes or 'compatible solutes', as they are named because they are compatible with cell metabolism. No far-going changes in the properties of the intracellular enzymatic machinery are needed to enable the cells to function at high salt. Examples of such osmotic solutes are glycerol in the alga *Dunaliella*, glycine betaine, ectoine and hydroxyectoine in many Bacteria, some Archaea, and even a few protists (eukaryotes). In the past it was assumed that organic osmotic solutes do not play a role in the physiology of the halophilic Archaea of the class *Halobacteria*. However, already two decades ago, 2-sulfotrehalose was found to be accumulated within the cells of a number of haloalkaliphilic members of the group such as *Natronococcus occultus*, and the compound functions there, together with high concentrations of KCl, to provide osmotic balance. In recent years, analysis of genome sequences of many members of the group has shown that the ability to synthesize trehalose and sulfotrehalose is more widespread among the Archaea than previously assumed.

Potassium chloride at high concentrations is not as 'compatible' to cellular metabolism as are the uncharged or zwitterionic osmotic solutes mentioned above. Therefore an organism that uses the 'salt-in' strategy for osmotic adaptation needs extensive adaptation of the entire intracellular enzymatic machinery to function in the presence of molar concentrations of KCl. This is the reason why most of the proteins encoded by the genomes of the *Halobacteria* have a strong acidic nature: they possess a large excess of negative charges due to their high content of the acidic amino acids glutamate and aspartate as compared to the positively charged amino acids lysine and arginine. Such acidic enzyme proteins are soluble and active in the presence of high salts, but many denature in low-salt solutions. As a result, the halophilic Archaea of the class *Halobacteria* cannot live in low-salt environments. As explained above, also the S-layer protein that makes up most of the cell envelope of most species needs high salt for stabilization, so that the cells lyse at low salt.

Species within the class *Halobacteria* generally lead an aerobic heterotrophic life style, and they are commonly grown in complex media containing high concentrations of yeast extract, casamino acids, and similar rich sources of nutrients. Amino acids and simple organic acids such as acetate, succinate, and pyruvate are among their favorite carbon and energy sources. Glycerol often stimulates growth. Many species can grow on defined media with a single organic carbon compound and inorganic sources of nitrogen, sulfur and phosphorus; others have complex nutritional demands.

Some members of the group are inhibited by high concentrations of organic substrates and can only be cultivated in nutrient-poor media. *Halosimplex carlsbadense*, isolated from a salt mine, only grows in defined medium with acetate and glycerol, acetate and pyruvate, or pyruvate alone. The flat square gas-vacuolated *Haloquadratum walsbyi* is another representative that only grows in low-nutrient media. Also here pyruvate is an important component of the media that enable the growth of this interesting organism that had defied all attempts toward its cultivation for nearly a quarter of a century since its discovery in 1980.

Carbohydrate metabolism was first investigated in *Halorubrum saccharovorum*. When grown on glucose as carbon and energy source, this organism degrades its substrate using a modified Entner-Doudoroff pathway in which the phosphorylation step is postponed: glucose is oxidized via gluconate to 2-keto-3-deoxygluconate, followed by phosphorylation to 2-keto-3-deoxy-6-phosphogluconate, which is then split into pyruvate and glyceraldehyde-3-phosphate. Members of the genera *Haloferax* and *Haloarcula* are also known for their ability to use simple sugars. Not all species grow on carbohydrates, and those that do often oxidize the substrate incompletely, leading to the formation of acids such as acetate, lactate, and sometimes also pyruvate.

The ability to produce exoenzymes such as proteases, amylases, lipases and nucleases is widespread among the halophilic Archaea, enabling them to use macromolecules such as proteins, starch, lipids and nucleic acids as sources of nutrients.

There are records of the isolation of halophilic Archaea, especially members of the genera *Haloferax* and *Haloarcula*, which can degrade aliphatic and aromatic hydrocarbons and other aromatic compounds. Compounds reported to be degraded include tetradecane, hexadecane, heptadecane, eicosane, heneicosane, the aromatic hydrocarbons acenaphthene, phenanthrene, anthracene, 9-methylanthracene, and other aromatic compounds such as benzoate, cinnamate, 3-phenylpropionate, and p-hydroxybenzoate. However, none of the type strains of the species that are available from culture collections is known to degrade such compounds.

As the solubility of gases in water decreases strongly with the increase in salt concentration, availability of oxygen may easily become a limiting factor for the development of halophilic Archaea. Some members of the group possess different modes of anaerobic growth. One of those mechanisms is based on the use of alternative electron acceptors. Nitrate is reduced to nitrite by many members of the *Halobacteria*, but this reaction is not coupled to anaerobic growth. Only in few species was anaerobic growth by denitrification documented. Thus, *Haloferax denitrificans*, *Haloarcula marismortui*, *Haloarcula vallismortis*, and *Haloquadratum walsbyi* can grow anaerobically using nitrate as an electron acceptor. Gaseous nitrogen and/or nitrous oxide are the products of nitrate reduction. Nitrate is not abundantly found in salt lakes and salterns, also because of the lack of activity of autotrophic

nitrification at high salt concentrations. Therefore it is not clear to what extent this type of metabolism is used by these organisms in their natural environments. Some species can grow anaerobically by reduction of dimethylsulfoxide, trimethylamine-*N*-oxide or fumarate, with dimethylsulfide, trimethylamine and succinate as the reduction products, respectively. Also for these processes the ecological relevance is not clear.

An interesting, recently discovered type of anaerobic respiration that is probably relevant ecologically is the use of elemental sulfur and other sulfur compounds as the electron acceptors by the strictly anaerobic acetotrophic *Halanaeroarchaeum sulfurireducens*. This species is a rare example of an obligatory anaerobic member of the *Halobacteria*. It was isolated from sediments and brines collected from hypersaline lakes in the Kulunda Steppe (Altai, Russia). Acetate and pyruvate are the only electron donors used, and elemental sulfur is the only electron acceptor that supports growth. In contrast to nearly all other members of the *Halobacteria* it lacks pink-red carotenoid pigments.

Even anaerobic lithoheterotrophic growth is possible in the group. The recently isolated *Halodesulfurarchaeum formicicum* (family *Halobacteriaceae*) grows anaerobically using hydrogen gas or formate as the electron donors and elemental sulfur, thiosulfate or dimethylsulfoxide as the electron acceptors. Organic nutrients are required as carbon source. This type of organism is probably widely distributed in hypersaline inland lakes, solar salterns, lagoons and deep submarine anoxic brines, and it may well play an important role in the biogeochemical cycle of sulfur in such environments.

The ability of *Halobacterium salinarum* and possibly a number of additional members of the group to grow photoheterotrophically in the absence of oxygen based on the light absorbed by the outward proton pump bacteriorhodopsin was mentioned above. However, sustained anaerobic growth under these conditions is not possible as a minimal amount of oxygen is still needed for the biosynthesis of the retinal prosthetic group by splitting of its precursor β -carotene.

Anaerobic fermentative metabolism was documented in a few members of the *Halobacteria* class. *Halobacterium* species grow anaerobically in the dark when L-arginine is added to the medium. Fermentation of arginine to citrulline, ammonia and CO₂ via ornithine and carbamoylphosphate provides the ATP necessary for growth. However, this ability was seldom found in other genera. Other types of fermentative metabolism may be possible in some species, but the pathways responsible for ATP generation were not documented. For example, this is the case for *Halorhabdus tiamatea* (*Haloarculaceae*), a non-pigmented, extremely halophilic archaeon isolated from the brine-sediment interface of the Shaban Deep, a hypersaline anoxic basin in the northern Red Sea. It uses yeast extract and starch as carbon and energy source.

Ecology

Massive presence of halophilic Archaea of the class *Halobacteria* in hypersaline lakes is often conspicuous thanks to their red-pink pigmentation. This phenomenon can be seen in the northern basin of Great Salt Lake, Utah, in Lake Urmia in Iran, and in other natural lakes at or approaching salt saturation. The same is true for man-made hypersaline environments: saltern crystallizer brines such as shown in Fig. 1 typically contain between 10⁷ and 10⁸ such red cells per milliliter. Other types of pigmented microorganisms (bacteria, unicellular algae rich in carotenoids) may also contribute to the coloration of the waters. Such red microbial blooms are not restricted to NaCl-dominated brines of neutral pH: they can be seen also in hypersaline soda lakes in eastern Africa and elsewhere where the pH is 9–10 or even higher. Alkaliphilic members of the family such as *Halorubrum vacuolatum*, *Natronomonas pharaonis*, *Natrialba magadii*, *Natronobacterium gregoryi* and *Natronococcus occultus* are characteristic inhabitants of hypersaline soda lakes.

Occasional blooms of red Archaea were also reported from the Dead Sea on the border between Israel and Jordan, a magnesium chloride-dominated lake with a slightly acidic pH. Some isolates from the Dead Sea such as *Haloferax volcanii*, *Halorubrum sodomense* and *Halobaculum gomorrense* are markedly tolerant to high concentrations of divalent cations such as Mg²⁺ and Ca²⁺, and they have a relatively low requirement for Na⁺.

There are very few known acidophilic or acid-tolerant members of the *Halobacteria*. *Halarchaeum acidiphilum* is the only truly acidophilic representatives of the group. It only grows within the narrow range between pH 4.1 and 4.8 with an optimum at pH 4.4 in the presence of 200 g l⁻¹ salt. Curiously, it was isolated from a sample of solar salt that had a slightly alkaline reaction. Temperatures up to 55°C are tolerated by many species. One cold-tolerant species is known: *Halorubrum lacusprofundi* isolated from Deep Lake, Antarctica. Its optimum growth is at 31–37°C, but it still can grow at temperatures as low as 4°C.

The first isolates described in the literature more than a hundred years ago, which are strains of the genera *Halobacterium* and *Halococcus*, were obtained from salted fish, salted meat and salted hides whose quality was negatively affected by the growth of red microorganisms. The source of those organisms may well have been the crude solar salt used for the preservation of the products. In other cases growth of such organisms is encouraged: during the preparation of certain salted fermented food products, e.g., nam pla, a fish sauce from Thailand, the proteases excreted by the Archaea contribute to the production process.

As high salt concentrations are necessary for growth of the halophilic Archaea, as well as for the stabilization of the S-layer cell walls of most species, we do not normally encounter such organisms in environments of seawater salinity and below. Still, viable cells of *Halococcus*, a genus that has a rigid polysaccharide cell wall, could be recovered from Mediterranean seawater. *Halococcus* species were also cultivated from the salt-excreting glands in the nostrils of certain seabirds. It is well possible that such birds can carry cells over long distances to colonize new hypersaline environments. Some other representatives of the *Halobacteria* have been found in environments with salinities similar to that of seawater or even below. Examples are *Halogeometricum pallidum* and *Haladaptatus paucihalophilus*, isolated from a low-salt, sulfide-rich spring in Oklahoma.

Members of the *Halobacteria* were recovered from rock salt deposited millions of years ago. Examples are *Halococcus salifodinae* and *Halosimplex carlsbadense*. Some halophilic Archaea may retain their viability for very long periods when trapped in fluid inclusions within halite crystals.

The Halophilic Methanogenic Archaea

Halophilic Archaea are not only found in the class *Halobacteria*. Also among the methanogenic Archaea we find true halophiles (Table 1). All methanogens are strict anaerobes. Most biogenic methane on Earth is produced by reduction of carbon dioxide by hydrogen and by splitting of acetate to yield methane and carbon dioxide. No acetoclastic methanogens are known to grow in hypersaline environments, probably because the amount of energy obtained in the reaction may be insufficient to supply the additional energy needed for osmotic adaptation. The most salt-tolerant methanogen known that derives its energy from CO₂ reduction with hydrogen is *Methanocalculus halotolerans* (order *Methanomicrobiales*). It was isolated from an oil well in Alsace, France. It can also use formate as energy source, and grows optimally at 50 g l⁻¹ NaCl. No growth is possible above 120 g l⁻¹.

The preferred substrate for growth of the truly halophilic methanogens is trimethylamine. This compound can be expected to occur in anaerobic hypersaline environments as a degradation product of glycine betaine, a compatible solute used for osmotic stabilization by many types of microorganisms. Trimethylamine is degraded to methane, carbon dioxide and ammonia. Dimethylsulfide, a degradation product of another osmotic solute, dimethylsulfoniopropionate, is another substrate for some halophilic methanogens. Methanogens convert it to methane, carbon dioxide and hydrogen sulfide.

The halophilic trimethylamine degrading methanogens all belong to the family *Methanosarcinaceae*, order *Methanosarcinales*. *Methanohalobium evestigatum*, *Methanohalophilus portucalensis* and *Methanosalsum zhilinae* grow at salt concentrations up to 240–250 g l⁻¹ salt. For osmotic stabilization they produce organic osmotic solutes: glycine betaine, β-glutamine, β-glutamate, and Nε-acetyl-β-lysine.

The Nanohaloarchaea

Metagenomic studies have recently revealed the existence of an additional group of extremely halophilic Archaea with very small cells, not yet represented by cultivated representatives. The novel group of *Euryarchaeota* known as 'Nanohaloarchaea', only distantly related to the *Halobacteria*, was found in different sites worldwide. One of those is Lake Tyrrell in NW Victoria, Australia (290 g l⁻¹ salt). These organisms are about 0.6 μm in diameter. Based on the analysis of their genomes, these nanohaloarchaea probably lead an aerobic photoheterotrophic life style, as the genes of biosynthesis of the bacteriorhodopsin protein and the retinal prosthetic group are present. Genes for the degradation of polysaccharides are also found. Two lineages of nanohaloarchaea from Lake Tyrrell were named '*Candidatus Nanosalinarum*' and '*Candidatus Nanosalina*'. In a 190 g l⁻¹ salinity saltern evaporation pond in Alicante, Spain, a related organism was characterized by single-cell genomics and was named '*Candidatus Haloredivivus*'.

Conclusion

We now have a good understanding of the biology of the aerobic halophilic Archaea of the class *Halobacteria*. Many different types have been cultured, and they are quite diverse with respect to their morphology, chemotaxonomic properties, growth conditions and possible modes of metabolism. Some representatives have become popular model organisms for the study of the group. Examples are *Halobacterium salinarum* strains used for genomic analysis, *Haloarcula marismortui* for protein structure, and *Haloferax volcanii* for genetic studies. We have cultured relatives closely related to nearly all those phylotypes belonging to the group that can be recognized in 16S rRNA gene libraries and in metagenomes prepared from most hypersaline environments. This is also true for the long-elusive flat square gas-vacuolated *Haloquadratum walsbyi*, recognized as a prokaryote in 1980 but first brought into culture only in 2004. Genomic comparisons have in recent years led to a highly improved taxonomic classification of the different members of the group, which is now divided into three orders and six families.

The *Halobacteria* are the best-known group of halophilic Archaea, but the archaeal domain contains additional members that are adapted to life at high salt concentrations. The family *Methanosarcinaceae* of methanogenic Archaea contains a number of halophilic representatives that can grow at salt concentrations close to saturation. Most members of this family are not halophilic, and the halophiles do not form a phylogenetically separate group as do the aerobic *Halobacteria*.

The recent discovery of the 'Nanohaloarchaea' during cultivation-independent studies based on DNA isolated from biomass collected from different hypersaline environments shows that the diversity of Archaea adapted to life at high salt concentrations is larger than assumed in the past. Based on the elucidation of their genome sequence we can deduce some information about their possible modes of life. The next challenge will be to obtain them in culture so that the organisms themselves, and not only their DNA, will become available for study.

Heavy Metal Pollutants: Environmental and Biotechnological Aspects[☆]

Geoffrey M Gadd, University of Dundee, Dundee, Scotland, United Kingdom

© 2019 Elsevier Inc. All rights reserved.

Glossary

Biomineralization The collective processes by which organisms form minerals.

Biosorption The removal of metal or metalloid species, compounds and particulates, radionuclides, and organometal(loid) compounds from solution by physico-chemical interactions with microbial or other biological materials.

Desorption Non-destructive elution and recovery of, for example, metal or metalloid species, radionuclides, and organometal(loid) compounds from loaded biological material by physico-chemical treatment(s).

Heavy metals An ill-defined group of biologically essential and inessential metallic elements, generally of density $>5 \text{ g cm}^{-3}$, exhibiting diverse physical, chemical, and biological properties with the potential to exert toxic effects on microorganisms and other life forms.

Metal resistance The ability of a microorganism to survive the toxic effects of heavy metal exposure by means of a detoxification mechanism, usually produced in response to the metal species concerned.

Metal tolerance The ability of a microorganism to survive the toxic effects of heavy metal exposure because of intrinsic properties and/or environmental modification of toxicity.

Metallothioneins Low-molecular-weight cysteine-rich proteins capable of binding essential metals (e.g., Cu and Zn) as well as inessential metals (e.g., Cd).

Organometallic compound A compound containing at least one metal–carbon bond, often exhibiting enhanced microbial toxicity. When such compounds contain ‘metalloid’ elements (e.g., Ge, As, Se, and Te), the term ‘organometalloid’ may be used.

Phytochelatin Metal-binding γ -Glu-Cys peptides of general formula $(\gamma\text{-Glu-Cys})_n\text{-Gly}$ (n generally 2–7); now designated as class III metallothioneins that are atypical, nontranslationally synthesized metal thiolate polypeptides. Cd-binding γ -Glu-Cys peptides from some yeasts are also called cadystins.

Siderophores Low-molecular-weight Fe(III) coordination compounds excreted by microorganisms, which enable the accumulation of iron from the external environment.

Abbreviations

γ -Glu-Cys	γ -glutamyl-cysteinyl
DMSe	Dimethyl selenide
EPS	Extracellular polymeric substances
SRB	Sulfate-reducing bacteria

Defining Statement

This article describes the roles of microorganisms in the transformation of heavy metals, as well as metalloids, organometals, and radionuclides, between soluble and insoluble phases, and the environmental and biotechnological importance of these transformation processes in biogeochemical cycles and in new biotechnologies for metal biorecovery and the treatment of metal, metalloid, and radionuclide pollution.

Introduction

Heavy metals comprise an ill-defined group of more than 60 metallic elements, of density higher than 5 g cm^{-3} , with diverse physical, chemical, and biological properties, but generally having the ability to exert toxic effects toward microorganisms. Many metals are essential for microbial growth and metabolism at low concentrations (e.g., Cu, Fe, Zn, Mg, Ni, Mo, Ca, Co, and Mn) but they are toxic in excess amounts, and both essential and inessential metal ions may be accumulated by the microbial cells by

[☆]*Change History:* June 2019. Geoffrey M. Gadd had updated Chapter and Bibliography. This is an update of Gadd, G.M., 2017. Heavy Metal Pollutants: Environmental and Biotechnological Aspects. Reference Module in Life Sciences. Elsevier.

This article is an update of Geoffrey M. Gadd, Heavy Metal Pollutants: Environmental and Biotechnological Aspects, *Reference Module in Life Sciences*, Elsevier, 2017.

physico-chemical and biological mechanisms. Thus, 'toxic metals' and 'potentially-toxic metals' are useful general terms. In this article, the term 'heavy metal' is used in a broad sense, and the discussion will include actinides, metal radionuclides, and organometal(loid) compounds. All these substances have a common potential for microbial toxicity and bioaccumulation, are of environmental significance as pollutants or because of introduction as biocides and other substances, and many are of great economic and industrial importance.

Environmental Aspects of Heavy Metal Pollution

Heavy Metals in the Environment

Although elevated levels of toxic heavy metals can occur in natural locations (e.g., volcanic soils and hot springs), average environmental abundances are generally low with most of that immobilized in sediments and ores being biologically unavailable. However, anthropogenic activities have disrupted natural biogeochemical cycles, and there is increased atmospheric release as well as deposition into aquatic and terrestrial environments. The major sources of pollution include fossil fuel combustion, mineral mining and processing, nuclear and other industrial effluents and sludges, brewery and distillery wastes, biocides, and preservatives including organometallic compounds. In fact, almost every industrial activity can lead to altered mobilization and distribution of heavy metals in the environment. Because of the fundamental microbial involvement in biogeochemical processes, as well as in plant and animal productivity and symbioses, toxic metal pollution can have significant short- and long-term effects and ultimately affect higher organisms, including humans, for example, by accumulation and transfer through food webs.

Effects of Heavy Metals on Microbial Populations

Metals exhibit a range of toxicities toward microorganisms, depending on physico-chemical and biotic factors. While toxic effects can arise from natural activities, toxic effects on microbial communities are more commonly associated with anthropogenic contamination or redistribution of toxic metals. This can arise from aerial and aquatic sources, as well as agricultural practices, industrial activity, and domestic and industrial wastes. In some cases, microbial activity can result in remobilization of metals from other wastes and transfer into aquatic systems. It is commonly accepted that toxic metals (and their chemical derivatives and related substances) can have significant effects on microbial populations, and almost every index of microbial activity can be affected.

For toxicity to occur, heavy metals must directly interact with microbial cells and/or indirectly affect growth and metabolism by interfering with, for example, nutrient uptake, or by altering the physico-chemical environment of the cell. A variety of non-specific and specific mechanisms (e.g., biosorption and transport, respectively) determine the entry of mobile metal species into cells, and if toxic thresholds are exceeded, cell death will result unless mechanisms for detoxification are possessed. The plethora of intracellular metal-binding ligands ensures that many toxic interactions are possible. Thus, practically every index of microbial activity can be adversely affected by toxic metal concentrations, including primary productivity, methanogenesis, nitrogen fixation, respiration, motility, biogeochemical cycling of C, N, S, P, and other elements, organic matter decomposition, enzyme synthesis and activity in soils, sediments, and waters.

Despite potential toxicity, many microorganisms still survive, grow, and flourish in apparently metal-polluted locations, and a variety of mechanisms, both active and incidental, contribute to resistance and tolerance. However, general conclusions about heavy metal effects on natural populations are difficult to make because of the complexity of metal speciation, toxicity in the environment, and the morphological and physiological diversity encountered in microorganisms. Furthermore, environmental perturbations associated with industrial metal pollution (e.g., extremes of pH, salinity, and nutrient limitations) may also have adverse effects on microbial communities. Nevertheless, it is commonly assumed that microbes are able to respond to metal contamination and maintain metabolic activity through changes in microbial community structure and selection for resistance. Resistance and tolerance are arbitrarily defined, frequently interchangeable terms, and often based on whether particular strains and isolates can grow in the presence of selected heavy metal concentrations in laboratory media. It is probably more appropriate to use 'resistance' to describe a direct mechanism resulting from heavy metal exposure, for example, bacterial reduction of Hg^{2+} to Hg^0 , or metallothionein synthesis by yeasts. 'Tolerance' may be a result of intrinsic biochemical and structural properties of the host, such as possession of impermeable cell walls, extracellular slime layers or polysaccharide, metabolite excretion, as well as environmental modification of toxicity. However, distinctions are difficult in many cases because several direct and indirect mechanisms, both physico-chemical and biological, can contribute to microbial survival. Thus, although heavy metal pollution can qualitatively and quantitatively affect microbial populations in the environment, it may be difficult to distinguish metal effects from those of environmental components, environmental influence on metal toxicity, and the nature of microbial resistance/tolerance mechanisms involved. Although some gross generalizations are possible regarding toxic metal influence on microbial communities, individual cases are likely to be site-specific and potentially complex.

Environmental Modification of Heavy Metal Toxicity

The physico-chemical characteristics of a given environment determine metal speciation and, therefore, chemical and biological properties of heavy metals. Concentration and speciation of metals in solution is governed by many processes, including inorganic and organic complexation, oxidation-reduction reactions, precipitation-dissolution, adsorption-desorption, some of these being mediated by microbial activities. Because major mechanisms of metal toxicity are a consequence of strong coordinating properties, a

reduction in bioavailability may reduce toxicity and enhance microbial survival. Such parameters as pH, temperature, aeration, soluble and particulate organic matter, clay minerals, and salinity can influence heavy metal speciation, mobility, and toxicity. Metals can exist in solution as free cations (e.g., Cu^{2+} , Cd^{2+} , and Zn^{2+}), as soluble complexes with inorganic or organic ligands (e.g., ZnCl^+ , CdCl^+ , and metal citrates), or in association with colloidal material. Common inorganic ligands that can complex metals include SO_4^{2-} , Cl^- , OH^- , PO_4^{3-} , NO_3^- , and CO_3^{2-} . Organic complexing agents include humic and fulvic acids, aromatic and aliphatic compounds, and carboxylic acids. Acidic conditions may increase metal availability, although H^+ may successfully compete with and reduce or prevent binding and transport. Environmental pH also affects metal complexation with organic components and inorganic anions (e.g., Cl^-). With increasing pH, there may be formation of hydroxides, oxides, and carbonates of varying solubility and toxicity. Some hydroxylated species may associate more efficiently with microbial cells than the corresponding metal cations. The oxidation state of several metals also determines solubility, for example, Cr(VI) being soluble and toxic and Cr(III) being immobile and less toxic. Such reductive transformations may be mediated by microbes, with accompanying consequences for survival. Colloidal materials of significance in affecting metal bioavailability and transport include iron and manganese oxides, clay minerals, and organic matter. Metals can precipitate as solid phases, for example, CdCO_3 , $\text{Pb}(\text{OH})_2$, ZnS , CuS , as well as mixed compounds. Toxic metals may also substitute for other metals in indigenous minerals, for example, Cd and Sr may substitute for Ca in CaCO_3 . In addition, toxic metals may sorb onto preexisting minerals. A reduction in toxicity in the presence of elevated concentrations of anions such as Cl^- , CO_3^{2-} , S^{2-} , and PO_4^{3-} is frequently observed. Mono-, di-, and multivalent cations may affect heavy metal toxicity by competing with binding and transport sites. Other synthetic and naturally produced soluble and particulate organic substances, including microbial metabolites, may influence toxicity by binding and complexation. Anionic contaminants, such as arsenic, selenium, and chromium oxyanions like AsO_4^{3-} , AsO_2^- , SeO_4^{2-} , SeO_3^{2-} , and CrO_4^{2-} , can sorb to positive charges on insoluble organic matter and iron, manganese, aluminum oxides, and carbonates. The removal of heavy metal species by intact living and dead microbial biomass, by physico-chemical and/or biochemical interactions, may also be significant in some locations. In more general terms, microbial growth and activity is influenced by environmental parameters, including the availability of organic and inorganic nutrients, and this can clearly affect the responses to potentially toxic metals.

Mechanisms of Microbial Heavy Metal Detoxification

Extracellular metal complexation, precipitation, and crystallization can result in detoxification. Polysaccharides, organic acids, pigments, proteins, and other metabolites can remove metal ions from solution and/or convert them into less toxic species. Iron-chelating siderophores may chelate other metals and radionuclides and possibly reduce their toxic effects. Oxalate excretion by fungi can result in precipitation of insoluble metal oxalates, e.g., Ca, Cu, Ni, Mn, Mg, Zn, Pb, Cd and La. The production of H_2S by microorganisms, for example, by *Desulfovibrio* sp., results in the formation of insoluble metal sulfides and also disproportionation of organometallics to volatile products as well as insoluble sulfides, for example:

Many other examples of metal crystallization, biomineralization and precipitation are known, and mediated by processes dependent and independent of metabolism. Some of these are of great importance in biogeochemical cycles and involved, for example, in microfossil formation, iron and manganese deposition, silver and uranium biomineralization, and the formation of stable calcareous minerals.

Decreased accumulation, sometimes as a result of efflux, and impermeability may be important survival mechanisms. Impermeability may be a consequence of cell wall and/or membrane composition, lack of transport mechanism, or increased turgor pressure. Bacterial plasmids have resistance genes to many toxic metals and metalloids, for example, Ag^+ , AsO_2^- , AsO_4^{3-} , Cd^{2+} , Co^{2+} , CrO_4^{2-} , Cu^{2+} , Hg^{2+} , Ni^{2+} , Sb^{3+} , TeO_3^{2-} , Tl^+ , and Zn^{2+} . Related systems are frequently located on bacterial chromosomes, for example, Hg^{2+} resistance in *Bacillus* spp., Cd^{2+} efflux in *Bacillus* spp., and arsenic efflux in *Escherichia coli*. Copper tolerance genes are generally genome-located. General conclusions in bacterial metal resistance include the following: (1) plasmid-determined resistances are highly specific; (2) resistance systems have been found on plasmids in all bacterial groups tested; and (3) resistance mechanisms generally involve efflux from the cells or enzymatic detoxification. However, other less-specific interactions, for example, sorption, may contribute to the overall response. Many bacterial metal resistance mechanisms, for example, Cd, Cu, and As, depend on efflux. Efflux pumps, determined by plasmid and chromosomal systems, are either ATPases or chemiosmotic systems, with mechanisms often showing similarity in different types of bacteria. Cd^{2+} resistance may involve (1) an efflux ATPase in Gram-positive bacteria, (2) cation- H^+ antiport in Gram-negative bacteria, and (3) intracellular metallothionein in cyanobacteria. Arsenic-resistant Gram-negative bacteria have an arsenite efflux ATPase and an arsenate reductase (which reduces arsenate [As(V)] to arsenite [As(III)]), which comprise the underlying biochemical mechanism. A Cd^{2+} efflux ATPase is widely found in Gram-positive bacteria, including species of *Bacillus*. Systems for Hg^{2+} resistance occur on plasmids from Gram-positive and Gram-negative bacteria with component genes being involved in the transport of Hg^{2+} to the detoxifying enzyme mercuric reductase, which reduces Hg^{2+} to elemental Hg^0 . The enzyme organomercurial lyase can break the C-Hg bond in organomercurials. The large plasmids of *Alcaligenes eutrophus* (now *Cupriavidus metallidurans*) have several toxic metal resistance determinants, for example, three for Hg^{2+} , one for Cr^{6+} , and two for divalent cations, *czc* (Cd^{2+} , Zn^{2+} , and Co^{2+} resistance) and *cmr* (Co^{2+} and Ni^{2+} resistance). *Czc*

functions as a chemiosmotic divalent cation/ H^+ antiporter. In *Enterococcus hirae* (previously *Streptococcus faecalis*), copper resistance is determined by two genes, *copA* and *copB*, which determine uptake and efflux P-type ATPases, respectively. Plasmid-determined Cu^{2+} resistance has been described in *Pseudomonas* sp., *Xanthomonas* sp., and *E. coli*. Chromosomal genes also affect Cu^{2+} transport and resistance by determining uptake, efflux, and intracellular Cu^{2+} binding. Bacterial arsenic resistance is plasmid-mediated in Gram-positive bacteria, and several mechanisms of plasmid-mediated tellurite resistance have been suggested, including reduction, reduced uptake, and enhanced efflux, although, as with Ag^+ , resistance does not appear to depend on reduction to the elemental form (Te^0).

As with bacteria, intracellular metal concentrations in fungi may be regulated by transport, including efflux mechanisms. Such mechanisms are involved in normal metal homeostasis but also have a role in the detoxification of potentially toxic metals. Reduced heavy metal uptake has been observed in many tolerant microbes, including bacteria, algae, and fungi, although this is dependent on environmental factors, including pH and ion competition. However, some resistant strains may accumulate more metal than sensitive parental strains because of more efficient internal detoxification. Inside the cells, metal ions may be detoxified by chemical components, which include metal-binding proteins, or compartmentalized into specific organelles. Metal-sequestering organic and inorganic molecules, for example, polyphosphate, have been implicated in several microbial groups, whereas metal-binding peptides and proteins, including metallothioneins and γ -Glu-Cys peptides (phytochelatins, cadystins), have been detected in all microbial groups examined. Metallothioneins are small, cysteine-rich polypeptides that can bind essential metals (e.g., Cu and Zn), in addition to non-essential metals (e.g., Cd). Metal-binding γ -glutamyl-cysteinyl peptides are short peptides of general formula $(\gamma\text{-Glu-Cys})_n\text{-Gly}$. Peptides of $n = 2\text{--}7$ are most common, and these are important detoxification mechanisms in algae as well as several fungi and yeasts. In *Schizosaccharomyces pombe*, the value of n ranges from 2 to 5, whereas in *Saccharomyces cerevisiae*, only an $n2$ isopeptide has been observed. Although $(\gamma\text{EC})_n\text{G}$ can be induced by a wide variety of metal ions, including Ag, Au, Hg, Ni, Pb, Sn, and Zn, metal binding has only been shown for a few, primarily Cd and Cu. For Cd, two types of complexes exist in *S. pombe* and *Candida glabrata*. A low-molecular-weight complex consists of $(\gamma\text{EC})_n\text{G}$ and Cd, whereas a high-molecular-weight complex also contains acid-labile sulfide. The $(\gamma\text{EC})_n\text{G-Cd-S}^{2-}$ complex has greater stability and higher Cd-binding capacity than a low-molecular-weight complex, and consists of a CdS crystallite core and an outer layer of $(\gamma\text{EC})_n\text{G}$ peptides. The higher binding capacity of sulfide-containing complex confers tolerance to Cd. In *S. pombe*, evidence has also been presented for vacuolar localization of $(\gamma\text{EC})_n\text{G-Cd-S}^{2-}$ complexes. The main function of *S. cerevisiae* metallothionein (yeast MT) is cellular copper homeostasis. However, induction and synthesis of MT as well as amplification of MT genes leads to enhanced copper resistance in *S. cerevisiae*. The fungal vacuole also has an important role in the regulation of cytosolic metal ion concentrations and the detoxification of potentially toxic metal ions. Metals preferentially sequestered by the vacuole include Mn^{2+} , Fe^{2+} , Zn^{2+} , Co^{2+} , Ca^{2+} , Sr^{2+} , Ni^{2+} , and the monovalent cations K^+ , Li^+ , and Cs^+ . The absence of a vacuole or a functional vacuolar H^+ -ATPase in *S. cerevisiae* is associated with increased sensitivity and largely decreased capacity of the cells to accumulate Zn, Mn, Co, and Ni, metals known to be mainly localized in the vacuole.

Chemical transformations of metal and metalloid species by microorganisms may also constitute detoxification mechanisms, for example, bacterial Hg^{2+} reduction to Hg^0 . However, plasmid-determined chromate resistance appears unconnected with chromate $[Cr(VI)]$ reduction to $Cr(III)$, resistance depending on reduced CrO_4^{2-} uptake. Similarly, plasmid-mediated Ag^+ resistance appears not to involve Ag^+ reduction to Ag^0 . In addition to these, other examples of reduction are carried out by bacteria, algae, and fungi (e.g., Au^{3+} to Au^0). Methylated metal and metalloid species may be volatile and lost from a given environment, for example, dimethyl selenide (DMSe). Methylation of Hg^{2+} , by direct and indirect microbial action, can result in the formation of CH_3Hg^+ and $(CH_3)_2Hg$. Arsenic methylation can be mediated by many organisms with compounds having the general structure $(CH_3)_nAsH_{3-n}$, and mono-, di-, and trimethylarsine ($n = 1\text{--}3$, respectively) being major volatile compounds. The reduction of arsenic oxyanions by reductase enzymes is also frequent and a determinant of As resistance. However, there appears no involvement of such reductases in biomethylation.

Organometallic compounds may be detoxified by sequential removal of alkyl or aryl groups. Organomercurials can be degraded by organomercurial lyase, whereas organotin detoxification involves sequential removal of organic groups from the tin atom:

It should be stressed that abiotic mechanisms of metal methylation and organometal(lloid) degradation also contribute to their transformation and redistribution in aquatic, terrestrial, and aerial environments. The relative importance of biotic and abiotic mechanisms is usually difficult to establish.

Biotechnological Aspects of Heavy Metal Pollution

Microbial Processes for Metal Removal and Biorecovery

Certain microbial processes can solubilize metals, thereby increasing their bioavailability and potential toxicity, whereas others immobilize them and thus reduce their bioavailability (Fig. 1). The relative balance between mobilization and immobilization varies depending on the organisms and their environment. As well as being an integral component of biogeochemical cycles for metals, these processes may be exploited for the treatment of contaminated solid and liquid wastes. Metal mobilization can be achieved by autotrophic and heterotrophic leaching, chelation by microbial metabolites and siderophores, and methylation, which can result in volatilization. Similarly, immobilization can result from sorption to cell components or exopolymers, transport and

Fig. 1 Diagram depicting the major mechanisms of microbial metal transformation between soluble and insoluble metal species. The relative balance between such processes will depend on the environment and associated physico-chemical conditions, the microorganism(s) involved as well as relationships with plants, animals, and anthropogenic activities. Chemical equilibrium between soluble and insoluble phases is influenced by abiotic components, including dead biota and their decomposition products, as well as other physico-chemical components of the environmental matrix, for example, pH, water, inorganic and organic ions, molecules, compounds, colloids, and particulates. Solubilization can occur by chemolithotrophic (autotrophic) and chemoorganotrophic (heterotrophic) leaching; siderophores and other complexing agents; redox reactions; methylation and demethylation; biodegradation of organoradionuclide complexes. Immobilization can occur by biosorption to cell walls, exopolymers, other structural components, and derived/excreted products; precipitation can be a result of metabolite release, for example, sulfide, oxalate, or reduction; transport, accumulation, intracellular deposition, localization and sequestration; adsorption and entrapment of colloids and particulates. The overall scheme is also affected by reciprocal interactions between biotic and abiotic components of the ecosystem, such as abiotic influence on microbial diversity, numbers and metabolic activity; ingestion of particulates and colloids (including bacteria) by phagotrophs; biotic modification of physico-chemical parameters including redox potential, pH, O_2 , CO_2 , other gases and metabolites, temperature, and nutrient depletion.

intracellular sequestration, or precipitation as insoluble organic and inorganic compounds, for example, oxalates, carbonates, sulfides, or phosphates. In addition, microbiologically mediated reduction of higher valency species may effect either mobilization, for example, $Mn(IV)$ to $Mn(II)$, or immobilization, for example, $Cr(VI)$ to $Cr(III)$, and $U(VI)$ to $U(IV)$. In the context of bioremediation, solubilization of metal contaminants provides a means for removal of metals from solid matrices such as soils, sediments, and industrial wastes. Alternatively, immobilization processes enable metals to be transformed in situ and in bioreactors into insoluble, chemically inert forms, as well as providing a means of metal biorecovery. The latter is especially important for valuable metals that are of great industrial and economic significance but where their security of supply is inhibited because of, e.g., natural shortages, inadequate recycling, inefficient extraction methods and geopolitical factors. Biotechnological development of microbial systems may provide an alternative or adjunct to conventional physico-chemical treatment methods for contaminated effluents, leachates and wastewaters. Growing evidence suggests that some microbe-related processes are economically competitive with existing treatments in mining and metallurgy.

Metal Solubilization

Chemolithotrophic (autotrophic) leaching

Most chemolithotrophic metal leaching is carried out by chemolithotrophic, acidophilic bacteria, which obtain energy from oxidation of $Fe(II)$ or reduced sulfur compounds and solubilize metals because of the resulting production of $Fe(III)$ and H_2SO_4 .

The microorganisms involved include sulfur-oxidizing bacteria (e.g., *Acidithiobacillus thiooxidans*), iron- and sulfur-oxidizing bacteria (e.g., *Acidithiobacillus ferrooxidans*), and iron-oxidizing bacteria (e.g., *Leptospirillum ferrooxidans*). As a result of sulfur and iron oxidation, metal sulfides are solubilized concomitant with the pH of their immediate environment being decreased, therefore resulting in solubilization of other metal compounds, including metals sorbed to soil and mineral constituents. Chemolithotrophic leaching of metal sulfides is well established for industrial-scale biomining processes, but it has also been used to solubilize metals from sewage sludge as well as remediate other metal-contaminated solid materials, including soil and red mud, the main waste product of Al extraction from bauxite. One two-stage soil treatment process used a mixture of sulfur-oxidizing bacteria to acidify metal-contaminated soil before treatment of the metal-loaded leachate with sulfate-reducing bacteria (SRB).

Chemoorganotrophic (heterotrophic) leaching

Many chemoorganotrophic (heterotrophic) fungi (and bacteria) can leach metals from industrial wastes, low-grade ores, and metal-bearing minerals. This occurs as a result of proton efflux, siderophores (for Fe(III)), and organic acids, for example, citric and oxalic. Organic acids provide a source of protons and a metal-complexing anion, for example, citrate, oxalate, with complexation being dependent on the metal/anion concentrations, pH, and metal complex stability constants. Organisms such as *Aspergillus niger* and *Penicillium simplicissimum* have been used to leach Zn, Cu, Ni, and Co from a variety of solid materials, including industrial filter dust, copper converter slag, lateritic ores, red mud, manganiferous minerals, and municipal waste fly ash. Citrate and oxalate can form stable complexes with a large number of metals. Many metal citrates are highly mobile and not readily degraded. Oxalic acid can act as a leaching agent for metals that form soluble oxalate complexes, including Al and Fe.

Siderophores are highly specific Fe(III) ligands (formation constant often $>10^{30}$) that are excreted by microorganisms to aid iron assimilation. Such assimilation may be improved by attachment to solid Fe oxides in soil. Although primarily produced as a means of obtaining iron, siderophores are also able to bind other metals such as magnesium, manganese, chromium (III), gallium (III), and radionuclides such as plutonium (IV).

Metal Immobilization

Biosorption

Biosorption (defined here as the microbial uptake of organic and inorganic metal, metalloid, and radionuclide species, both soluble and insoluble, by physico-chemical mechanisms) may be influenced by metabolic activity (in living cells), and may also provide nucleation sites for the formation of stable minerals, including phosphates, sulfides, and oxides. Crystallization of elemental gold and silver may occur as a result of reduction, whereas the formation of hydrolysis products can enhance precipitation of U and Th. All biological macromolecules have an affinity for metal species with cell walls and associated materials being of the greatest significance in biosorption (Table 1). Moreover, mobile cationic species can be accumulated by cells via transport systems of varying affinity and specificity, and internally bound, transformed, precipitated, localized within organelles, or translocated to specific structures depending on the metal concerned and the organism.

Biosorption by cell walls and associated components

In bacteria, peptidoglycan carboxyl groups are the main cationic binding sites in Gram-positive species, with phosphate groups contributing significantly in Gram-negative species. Chitin, phenolic polymers, and melanin are important structural components of fungal walls, and these are also effective biosorbents for metals and radionuclides. Fungi can be efficient sorbents of metal ions over a wide range of pH values, and although they may take up less metal per unit dry weight than clay minerals (the most important metal-sorbing component in soil), they are more efficient sorbents per unit surface area. Variations in the chemical behavior of metal species as well as the composition of microbial cell walls and extracellular materials can result in wide differences in biosorptive capacities (Table 1). Extracellular polymeric substances (EPS), a mixture of polysaccharides, mucopolysaccharides, and proteins, can bind significant amounts of potentially toxic metals and entrap precipitated metal sulfides and oxides. One process uses floating mats of cyanobacteria, the metal-binding process being due to large polysaccharides ($>200\,000$ Da).

The ability of surface-associated macromolecules to effect the immobilization of aqueous metal(loid) species may be of great importance, particularly where organisms grow as surface-attached biofilms, enmeshed in a matrix of EPS. The biofilm mode of growth is now widely accepted to be the predominant form in which natural microbial populations occur, and it appears that natural mixed-species biofilms can act as sinks for precipitated minerals, including potentially toxic metals, in aqueous environments. The biofilm–EPS matrix can act as a direct adsorbent of dissolved metal ions, with the ionic state and charge density of EPS components determining the ionic binding and electrostatic immobilization properties. Bacterial EPS are dominated by polysaccharides, but secreted polymers also include proteins, nucleic acids, peptidoglycan, lipids, and phospholipids. This heterogeneous matrix generally has a net negative charge, with polyanionic moieties acting as an ion-exchange matrix for metal cations. Well-characterized examples include the propensity of uronic acid-containing polysaccharides to bind with carboxyl groups and thus bind metals, whereas neutral carbohydrates can bind metals by the formation of weak electrostatic bonds around the hydroxyl groups. Cross-linking of extracellular polysaccharides by metal ions themselves may alter the mechanical and chemical properties of EPS.

The biofilm growth mode appears to further enhance metal removal in various ways. Biosorption and bioprecipitation can be interrelated phenomena, such that ionic concentration by sorption at low-energy cellular, or EPS surface sites within biofilms can

Table 1 Examples of microbial metal and actinide accumulation to industrially significant levels. Data is derived from a number of sources and presented without reference to important experimental conditions, for example, metal and biomass concentration, pH, and whether freely suspended, living, dead or immobilized, or the mechanism of accumulation. In most cases, highest uptake levels are due to general biosorptive mechanisms

initiate mineral formation and immobilization within biofilms. Mineral precipitates formed in the bulk solution may also be physically entrapped or chemically adsorbed by the biofilm EPS matrix.

Biosorption by free and immobilized biomass

Both freely suspended and immobilized biomass from bacterial, cyanobacterial, algal, and fungal species have received attention with immobilized systems appearing to possess several advantages over 'free' biomass, including higher mechanical strength and easier biomass/liquid separation. Living or dead biomass of all groups has been immobilized by encapsulation or cross-linking using supports, which include agar, cellulose, alginates, cross-linked ethyl acrylate-ethylene glycol dimethylacrylate, polyacrylamide, silica gel, and cross-linking reagents, such as toluene diisocyanate and glutaraldehyde. Immobilized living biomass has mainly taken the form of bacterial biofilms (see "Biosorption by cell walls and associated components") on inert supports, and has been used in a variety of configurations, including rotating biological contactors, fixed-bed reactors, trickle filters, fluidized beds, and airlift bioreactors.

Metal desorption

Biotechnological exploitation of biosorption may depend on the ease of biosorbent regeneration for metal recovery. Metabolism-independent processes are frequently reversible by nondestructive methods, and hence can be considered analogous to conventional ion exchange. Most work has concentrated on nondestructive desorption, which should be efficient, cheap, and result in minimal damage to the biosorbent. Dilute mineral acids (~ 0.1 M) can be effective for metal removal, although more concentrated acids or lengthy exposure times may result in biomass damage. It may be possible to apply selective desorption of metalloid species from a loaded biosorbent using an appropriate elution scheme. For example, metal cations (e.g., Cu^{2+} , Cr^{3+} , Ni^{2+} , Pb^{2+} , Zn^{2+} , Cd^{2+} , and Co^{2+}) were released from algal biomass using eluant at pH 2, whereas at higher pH values, anionic metal species (e.g., SeO_4^{2-} , CrO_4^{2-} , and MoO_4^{2-}) were removed. Au^{3+} , Ag^+ , and Hg^{2+} , however, remained strongly bound at pH 2, and these were removed by the addition of ligands that formed stable complexes with these metal ions. Carbonates and/or bicarbonates are efficient desorption agents with potential for cheap, non-destructive metal recovery. Operating pH values for bicarbonates cause little damage to the biomass, which may retain at least 90% of the original uptake capacity.

Metal-binding proteins, polysaccharides, and other biomolecules

A diverse range of specific and nonspecific metal-binding compounds are produced by microorganisms. Non-specific metal-binding compounds are metabolites or by-products of microbial metabolism and range from simple organic acids and alcohols to macromolecules, such as polysaccharides, humic and fulvic acids. Specific metal-binding compounds may be produced in response to external levels of metals. Siderophores are low-molecular-weight Fe(III) coordination compounds (500–1000 Da) excreted under iron-limiting conditions by iron-dependent microorganisms. Although specific to Fe(III), siderophores can also complex Pu(IV), Ga(III), Cr(III), scandium (Sc), indium (In), nickel, uranium, and thorium. Specific, low-molecular-weight (6000–10 000 Da) metal-binding metallothioneins are produced by animals, plants, and microorganisms in response to the presence of toxic metals. Metal-binding γ -Glu-Cys peptides (phytochelatins and cadystins) contain glutamic acid and cysteine at the N-terminal position, and have been identified in plants, algae, and several microorganisms. The metal-binding abilities of siderophores, metallothioneins, phytochelatins, and other similar molecules may have potential for bioremediation of waters containing low metal concentrations, although few examples have been rigorously tested.

Transport and accumulation

Microbial metal transport systems are of varying specificity, and essential and non-essential metal(loid) species may be accumulated. The rates of uptake can depend on the physiological state of cells as well as the nature of environment or growth medium. Integral to the transport of metal ions into cells are transmembrane electrochemical gradients, for example of H^+ , resulting from the operation of enzymatic pumps (ATPases) that transform the chemical energy of ATP into this form of biological energy. ATPases are also involved in ion efflux in a variety of organisms and organellar ion compartmentation in eukaryotes via operation across vacuolar membranes. Metals may also enter (and leave) cells via pores or channels. With toxic heavy metals, permeabilization of cell membranes can result in exposure of intracellular metal-binding sites and increase passive accumulation. Intracellular uptake may result in death of sensitive organisms, unless a means of detoxification is possessed or induced (Fig. 2). Other mechanisms of microbial metal accumulation include iron-binding siderophores and co-transport of metals with organic substrates.

Metal precipitation and biomineralization

Precipitation by redox processes: Metal-reducing bacteria and iron oxidizers

A diverse range of microorganisms can use oxidized metallic species, for example, Fe(III), Cr(VI), or Mn(IV), as terminal electron acceptors. Many use more than one metal or anion, such as nitrate or sulfate. Fe(III) and Mn(IV) appear to be the most commonly utilized metals as terminal electron acceptors in the biosphere. However, since the solubility of both Fe and Mn is increased by reduction, other metals have been targeted in waste treatment, for example, molybdenum(VI) and Cr(VI). The reduction of, for example, Cr(VI) to Cr(III), by organisms including *Enterobacter cloacae* and *E. coli*, may facilitate removal by biosorption or (bio) precipitation. One potential application of dissimilatory biological metal reduction is uranium precipitation by reduction of soluble U(VI) compounds to U(IV) compounds, such as the hydroxide or carbonate, which have low solubility at neutral pH. Strains of *Shewanella* (*Alteromonas*) *putrefaciens* and *Desulfovibrio* sp. can produce a very pure precipitate of U(IV) carbonate. Such

Fig. 2 Mechanisms involved in the detoxification of metals including mechanisms that restrict entry into the cell and intracellular detoxification or organellar compartmentation, the latter occurring in some eukaryotes, for example, fungi. Operation of several mechanisms is possible depending on the organism and the cellular environment, some dependent and/or independent of metabolism. A variety of mechanisms may be involved in transport phenomenon contributing to decreased uptake and/or efflux. A variety of specific or nonspecific mechanisms may also affect redox transformations, intracellular chelation, and intracellular precipitation.

bacterial uranium reduction can also be combined with chemical extraction methods. The solubility of some other radionuclides, for example, Ra and Pu, may be increased by reduction, which may favor removal from, for example, contaminated soil.

Bacterial Fe oxidation is ubiquitous in environments with sufficient Fe^{2+} and conditions to support bacterial growth such as drainage waters and tailing piles in mined areas, pyritic and hydric soils (bogs and sediments), drain pipes and irrigation ditches, and plant rhizospheres. Iron oxidizers commonly found in acidic soil environments are acidophilic chemolithotrophs, such as *A. ferrooxidans*, significant for their role in generating acid mine drainage. Fungi, too, oxidize metals in their environment. Desert varnish is an oxidized metal layer (patina), of few millimeter thickness, found on rocks and in soils of arid and semi-arid regions, and is believed to be of fungal and bacterial origin.

Sulfate-reducing bacteria

SRB are strictly anaerobic heterotrophic bacteria found in environments where carbon substrates and sulfate are available. These utilize an energy metabolism in which the oxidation of organic compounds or hydrogen is coupled to the reduction of sulfate as the terminal electron acceptor, producing sulfide that often reaches significant concentrations in sediments or bioreactors:

Sulfur in S(VI) oxidation state is stoichiometrically reduced to S(-II) and, under circumneutral conditions in which SRB are generally encountered, the main product is bisulfide (HS^-), with a small proportion of volatile H_2S . Bisulfide is a highly reactive species, with the propensity to bind with metal cations in solution-forming metal sulfide solids. This is the main mechanism whereby SRB remove toxic metals from solution, for example,

The solubility products of most heavy metal sulfides are very low, in the range of 4.65×10^{-14} (Mn) to 6.44×10^{-53} (Hg), so that even a moderate output of sulfide can remove metals to safer levels permitted in the environment. SRB can create extremely reducing conditions, which can chemically reduce metals such as uranium(VI). In addition, sulfate reduction partially eliminates

acidity from the system, which can result in further precipitation of metals, for example, Cu, Al, as hydroxides as well as increasing the efficiency of sulfide precipitation.

Secondary metal(loid) removal by adsorption on SRB-produced metal sulfides deposited within, or immobilized by, the biofilm matrix can also contribute to overall removal. SRB-generated metal sulfides can adsorb a range of cations and anions. Fe(II) sulfides can bind a range of metals, allowing the level of metals in solution to be reduced from original concentrations in the order of mg l^{-1} to $\mu\text{g l}^{-1}$.

Processes utilizing metal sulfide precipitation

Sulfate reduction can provide both in situ and ex situ metal removal from acid mine drainage and, together with other mechanisms such as biosorption, it contributes to the removal of metals and acidity in artificial and natural wetlands. Large-scale bioreactors have also been developed using bacterial sulfate reduction for treating metal-contaminated waters. The best known commercial application involving metal sulfide precipitation is the THIOPAQ technology, developed and marketed by Paques Bio Systems B.V., Balk, the Netherlands (See Relevant Website section), and first applied in 1992 for the treatment of contaminated groundwater at the Budelco zinc refinery in the Netherlands. The basic THIOPAQ system consisted of a two-stage biological process in series: anaerobic sulfate reduction to sulfide followed by aerobic sulfide oxidation to elemental sulfur. Since the solubilities of most metal sulfides are much lower than those of their hydroxides, an advantage of the THIOPAQ system is that considerably lower effluent metal concentrations can be achieved than in the neutralization processes, which immobilize metals by hydroxide precipitation. In addition, the metal sulfide precipitate formed may be reprocessed in a smelter or a refinery.

Electron donors suitable for small-scale THIOPAQ installations were ethanol, various fatty acids, and organic waste streams. For large-scale applications, where more than 2.5 tons of hydrogen sulfide are produced per day, hydrogen gas is preferentially used as a reductant. Hydrogen gas can be produced on-site by cracking methanol or by steam-reforming natural gas or LPG. The main reaction that occurs in a reactor operated with H_2 is:

Hydrogen sulfide in the reactor gas (3%–15%, v/v) can be employed for metal precipitation. Compared to the addition of a NaHS or Na_2S solution, an advantage with the use of H_2S is that sodium is not introduced into the system. It is also possible that careful control of the pH and the redox potential of the process liquid may allow selective recovery of metals. Thus, sulfide precipitation makes it possible to separate copper from zinc, arsenic from copper, iron from nickel, and so on, in multiple reaction stages at different pH values. Alternatively, metals may also be precipitated as sulfides inside the anaerobic bioreactor.

At the Budelco zinc refinery in Budel-Dorp, the Netherlands, a THIOPAQ system capable of processing approximately $300 \text{ m}^3 \text{ h}^{-1}$ of polluted groundwater has been in operation since 1992. Its products, a metal sulfide sludge (mainly ZnS) and sulfur slurry, are fed back to the roasters in the refinery. The capacity of the installation was increased to $400 \text{ m}^3 \text{ h}^{-1}$ (in 1998), with the feed also including a mixture of groundwater and process water. Another THIOPAQ installation (called Budelco II, in operation since 1999) treated several bleed streams and process water: sulfate reduction occurs in a 500 m^3 bioreactor where hydrogen is used as the electron donor.

Another process, integrating bacterial sulfate reduction with bioleaching by sulfur-oxidizing bacteria, was developed to remove contaminating toxic metals from soils. In this process, sulfur- and iron-oxidizing bacteria were employed to release metals from soils by the breakdown of sulfide minerals and production of sulfuric acid, which liberates acid-labile forms such as hydroxides, carbonates, or sorbed metals. Metals are liberated in the form of an acid sulfate solution, which enables both the large proportion of acidity and almost the entirety of metals to be removed by bacterial sulfate reduction. Precipitation efficiency is further increased by the addition of flocculating agents.

In confined systems, SRB can also bring about significant increases in bulk pH, which can enhance sulfide precipitation and lead to precipitation of hydroxides and carbonates of transition metals. When an organic substrate acts as the electron donor, bicarbonate is also generated:

This has useful implications for the use of SRB in the remediation of acidic metal-processing waters and mine wastes, particularly where they are active within suspended or surface-attached mesophilic biofilms. SRB are reported to contribute significantly to metal removal in constructed wetlands as well as in alkalization of acidic mine wastes. Both sulfide generation and pH-related precipitation appear to be important. However, some studies have questioned the contribution of SRB in these broad-scale systems, arguing that Fe(III)-reducing bacteria make a greater contribution where carbon is limiting, in terms of both metal removal and ameliorating low pH.

There is also evidence that extremely reducing conditions that develop during sulfate reduction can lead to chemical conversion of oxyanions into cationic species, which can be more easily precipitated or biosorbed. The indirect chemical reduction of Cr(VI), as soluble chromate (CrO_4^{2-}), to much less soluble Cr(III) cationic species by sulfide and/or Fe^{2+} in SRB culture appears to be at least partially responsible for the removal of chromate from solution by SRB.

Phosphatase-mediated metal phosphate precipitation

In this process, metal or radionuclide accumulation by bacterial (e.g., *Citrobacter* sp.) biomass is mediated by a phosphatase enzyme induced during metal-free growth, which liberates inorganic phosphate from a supplied organic phosphate donor molecule, for example, glycerol 2-phosphate. Metal/radionuclide cations are then precipitated as phosphates on the biomass to high levels. In addition, metal precipitation by secreted phosphate generated from polyphosphate hydrolysis has also been suggested as a mechanism to remove metals and actinides from aqueous waste streams. Fungi are also capable of mediating metal precipitation as phosphates, e.g., U, Pb, from organic or inorganic phosphate sources.

High-gradient magnetic separation

Metal ion removal from solution has been achieved using bacteria rendered susceptible to magnetic fields. 'Non-magnetic' bacteria can be made magnetic by the precipitation of metal phosphates (aerobic) or sulfides (anaerobic) on their surfaces, as described previously. For those organisms producing iron sulfide, it has been found that this compound is not only magnetic but also an effective adsorbent for metallic elements.

Biomineralization

Apart from sulfides, microbes can also mediate formation of several inorganic and organic biominerals, e.g., oxalates, phosphates, oxides and carbonates, which lead to metal immobilization. Biomineralization refers to the collective processes by which organisms form minerals. Mineral synthesis can be categorized into biologically-induced mineralization (BIM) and biologically-controlled mineralization (BCM). Biologically-induced mineralization is where an organism modifies its local microenvironment creating conditions such that there is extracellular chemical precipitation of mineral phases. The organism does not appear to control the biomineralization process in BIM while a great degree of control over biomineralization is exerted by the organism in BCM, e.g., magnetosome formation in magnetotactic bacteria, and complex cellular biomineral structures in certain eukaryotes. Biomineralization provides other potential means of metal biorecovery, detoxification or bioremediation.

Most biomineralization examples of relevance to environmental biotechnology relate to biologically-induced mineralization. This can result from microbial oxidation or reduction of a metal species (as mentioned above), metabolite excretion, e.g., sulfide, oxalate, and other metabolism-dependent transformations of metal species, with microbial surfaces providing chemically-reactive sites for sorption ($\equiv$ biosorption) which can also lead to the nucleation and formation of mineral precipitates. Microbial cell surfaces can bind metal ions, inorganic anions, and even preformed nanominerals leading to fine-grained mineral phases on cell surfaces.

Calcium oxalate is the most common form of oxalate encountered in the environment, mostly occurring as the dihydrate (weddelite) or the more stable monohydrate (whewellite). Fungi can also produce other metal oxalates on interacting with a variety of different metals and metal-bearing minerals, e.g., Ca, Cd, Co, Cu, Mg, Mn, Sr, Zn, Ni and Pb. Many bacterial species can oxidize manganese which is then deposited on cells, sheaths, or spores as oxides. Some promote oxidation non-enzymatically, others enzymatically with possible involvement of a multicopper oxidase system, and include spore-forming and non-spore-forming rods, sheathed and appendaged bacteria as well as the usual morphological forms of Gram-positive and -negative bacteria from a diverse range of freshwater, marine and terrestrial ecosystems. Several fungi can also promote Mn(II) oxidation to Mn(IV)O₂ including *Acremonium* spp. In many cases, fungal oxidation is probably non-enzymatic and due to interaction with a metabolic product (e.g., a hydroxy acid) or a cellular component although the involvement of laccase and/or multicopper oxidases have been shown in ascomycetes. Mn oxide phases have high sorption capacities for numerous metal cations (e.g., Ni, Zn, Cu, Co, Mn, Pb, and Cd), and also serve as strong oxidants for inorganic [e.g., As(III) to As(V); Cr(III) to Cr(IV)] and organic compounds such as humic substances. Microbes can play a role in the formation of phosphate minerals such as vivianite (Fe₃(PO₄)₂·8H₂O), strengite (FePO₄·2H₂O), and variscite (AlPO₄·2H₂O). Secondary mycogenic uranium mineral precipitates on fungal mycelia growing in the presence of uranium oxides or depleted uranium were found to be uranyl phosphate minerals of the meta-autunite group, uramphite and/or chernikovite.

Metal, Metalloid, and Organometal Transformations

Microorganisms can transform certain metal, metalloid, and organometallic species by oxidation, reduction, methylation, or dealkylation. Biomethylated derivatives are often volatile and may be eliminated from a system by evaporation. The two major metalloid transformation processes described are reduction of metalloid oxyanions to elemental forms and methylation.

Microbial Reduction and Oxidation of Metalloid Oxyanions

The reduction of selenate (Se(VI)) and selenite (Se(IV)) to elemental selenium can be catalyzed by numerous microbes, which can result in a red precipitate deposited around the cells and colonies. Some bacteria use SeO₄²⁻ as a terminal *e*⁻ acceptor in dissimilatory reduction as well as reduce and incorporate Se into organic components, for example, selenoproteins (assimilatory reduction). Selenate (SeO₄²⁻) and selenite (SeO₃²⁻) can be reduced to Se⁰, with SeO₃²⁻ reduction appearing more ubiquitous than

SeO_4^{2-} reduction. However, only SeO_4^{2-} can support bacterial growth under anaerobic conditions: SeO_4^{2-} reduction to Se^0 is a major sink for Se oxyanions in anoxic sediments. Anaerobic SRB like *Desulfovibrio desulfuricans* can reduce selenate/selenite to Se^0 , but neither oxyanion could be used for respiratory growth. Reduction to Se^0 can be considered a detoxification mechanism. Reduction of TeO_3^{2-} to Te^0 is also a means of detoxification found in bacteria and fungi, with Te^0 being deposited in or around the cells, resulting in black colonies. The opposite process of Se^0 oxidation can occur in soils and sediments. It is possible that Se^0 oxidation is similar to S oxidation, and may be mediated by heterotrophs and lithotrophs. In aerobic soil slurries, Se^{4+} is the main product with lower amounts of Se^{6+} being produced; heterotrophic and autotrophic thiobacilli were believed to be the active organisms.

The extreme reducing conditions that SRB create can also result in indirect chemical reduction of metal(loid) and radionuclide species. This appears to be the case for U(VI), which is reduced chemically to U(IV) under highly reducing, sulfidic conditions. The ability of SRB to enzymatically reduce uranium is now established, and there has been some debate as to the relative contribution of chemical and enzymatic uranium reduction, with chemical reduction rates appearing relatively low. Nevertheless, while enzymatic reduction is effective in non-metabolizing cells, some studies appear to support a role for chemical reduction in the presence of growing cells.

Technetium (which, as ^{99}Tc , is a long half-life product of the nuclear fuel cycle) is present in many environments as Tc(VII) in the form of highly mobile pertechnetate ion (TcO_4^-). Chemical and enzymatic reductive precipitation of Tc has been demonstrated in SRB, in that chemical precipitation appears to be more efficient for uranium, with sulfide as a reductant. Under sulfidogenic conditions, chemical precipitation is operated in preference to enzymatic reduction, and *D. desulfuricans* was able to precipitate Tc extracellularly, probably as sulfide.

In contrast to reductive precipitation of metal(loid) described above, arsenic reduction frequently increases the solubility of this toxic element. Microbial dissimilatory reduction of As(V) to As(III) has been identified as an important route for increased As toxicity in the environment. This capacity appeared, for some time, to be phylogenetically and metabolically separate from dissimilatory sulfate reduction, but a *Desulfotomaculum* strain has the capability to simultaneously reduce arsenic and sulfate and to stimulate the precipitation of As(III) sulfide. The capacity of SRB to reduce and solubilize As and for soluble As(III) to precipitate with sulfide has further potential for bioremediation.

Methylation of Metalloids

Microbial methylation of metalloids to yield volatile derivatives, for example, dimethyl selenide, dimethyl telluride, or trimethylarsine, can be effected by a variety of bacteria, algae, and fungi. Bacteria and fungi are the most important Se-methylators in soil, with the most frequently produced volatile being dimethyl selenide. Selenium methylation appears to involve the transfer of methyl groups as carbonium (CH_3^+) ions via the S-adenosyl methionine system. Arsenic compounds such as arsenate (As(V), AsO_4^{3-}), arsenite (As(III), AsO_2^-), and methylarsonic acid ($\text{CH}_3\text{H}_2\text{AsO}_3$), can be methylated to volatile dimethylarsine ($(\text{CH}_3)_2\text{HAs}$) or trimethylarsine ($(\text{CH}_3)_3\text{As}$). Environmental factors that affect microbial activity can markedly affect Se methylation, for example, pH, temperature, organic amendments, Se speciation; however, the addition of organic amendments can stimulate methylation. The opposite process of demethylation can also occur in soil and water systems. Anaerobic demethylation may be mediated by methylotrophic bacteria.

Microbial Metalloid Transformations and Bioremediation

In situ immobilization of SeO_4^{2-} , by reduction to Se^0 , has been achieved in Se-contaminated sediments. Microbial methylation of selenium, resulting in volatilization, has also been used for in situ bioremediation of selenium-containing land and water at Kesterson Reservoir in the United States. Selenium volatilization from soil was enhanced by optimizing soil moisture, particle size, and mixing, while waters it was stimulated by the growth phase, salinity, pH, and selenium concentration. Se-contaminated agricultural drainage water was evaporated to dryness until the sediment selenium concentration approached $100 \text{ mg Se kg}^{-1}$ dry weight. Conditions such as carbon source, moisture, temperature, and aeration were then optimized for selenium volatilization, and the process continued until selenium levels in sediments declined to acceptable levels. Some potential for ex situ treatment of selenium-contaminated waters has also been demonstrated.

Mercury and Organometals

Key microbial transformations of inorganic Hg^{2+} include reduction and methylation. The mechanism of bacterial Hg^{2+} resistance is enzymic reduction of Hg^{2+} to nontoxic volatile Hg^0 by mercuric reductase. Hg^{2+} may also arise from the action of organomercurial lyase on organomercurials. Since Hg^0 is volatile, this could provide one means of mercury removal. Methylation of inorganic Hg^{2+} leads to the formation of more toxic volatile derivatives; the bioremediation potential of this process (as for other metals and metalloids, besides selenium, capable of being methylated, e.g., As, Sn, and Pb) has not been explored in detail. In addition to organomercurials, other organometals may be degraded by microorganisms. Organoarsenicals can be demethylated by bacteria, while organotin degradation involves sequential removal of organic groups from the tin atom. In theory, such mechanisms and interaction with bioremediation possibilities described previously may provide a means of detoxification.

The Mycorrhizosphere

Nearly all land plants depend on symbiotic mycorrhizal fungi. Two main types of mycorrhizas include endomycorrhizas where the fungus colonizes the interior of host plant root cells (e.g., ericoid and arbuscular mycorrhizas) and ectomycorrhizas where the fungus is located outside plant root cells. Mycorrhizal fungi are involved in proton-promoted and ligand-promoted metal mobilization from mineral sources, metal immobilization within biomass, and extracellular precipitation of mycogenic metal oxalates. Mycorrhizal associations may also be used for metal clean-up in the general area of phytoremediation. Mycorrhizas may enhance phytoextraction directly or indirectly by increasing plant biomass, and some studies have shown increased plant accumulation of metals, especially when inoculated with mycorrhiza isolated from metalliferous environments. Mycorrhizal metal immobilization around plant roots, including biomineral formation, may assist soil remediation and revegetation. Naturally occurring soil organic compounds can stabilize potentially toxic metals like Cu, Cd, Pb, and Mn. The insoluble glycoprotein, glomalin, produced in copious amounts on hyphae of arbuscular mycorrhizal fungi can sequester metals, and could be considered a useful stabilization phenomenon in the remediation of polluted soils.

Concluding Remarks

Microorganisms play important roles in the environmental fate of toxic metals, metalloids, and radionuclides with physico-chemical and biological mechanisms effecting transformations between soluble and insoluble phases. Such mechanisms are important components of natural biogeochemical cycles for metals and associated elements, for example, sulfur and phosphorus, with some processes being of potential application to the treatment of contaminated materials. The removal of such pollutants from contaminated solutions by living or dead microbial biomass and derived or excreted products may provide a means for element recovery and environmental protection. Although the biotechnological potential of some of these processes has only been explored in the laboratory or pilot scale, some mechanisms, notably bioleaching, biosorption, and precipitation, have been employed at a commercial scale. Of these, chemolithotrophic leaching is an established major process in mineral extraction but has also been applied to the treatment of contaminated land. There have been several attempts to commercialize biosorption using microbial biomass but success has been short-lived, primarily due to competition with commercially produced ion exchange media. Bioprecipitation of metals as sulfides has achieved large-scale application, and this holds out promise for further commercial development. Exploitation of other microbiological processes will undoubtedly depend on a number of scientific, economic, and political factors. A recent driver for fuller understanding and development of microbial processes for metal biorecovery arises from the need to safeguard the security and supply of valuable elements critical to new technologies in energy, the digital economy, computing and electronics, and for production of novel nanoscale biomineral and biometal forms with useful electrochemical and catalytic properties.

Introduction

More than half the world's population carries *Helicobacter pylori*. This Gram-negative organism colonizes specifically the stomach. Coexistence with humans may provide the host with benefits, especially in childhood, but prolonged infection frequently leads to disease including chronic gastritis and peptic ulcer disease. *H. pylori* infection was identified as a major risk for the development of gastric non-cardiac adenocarcinomas, and MALT (mucosa-associated lymphoid tissue) lymphoma. The World Health Organization classified *H. pylori* as a type I carcinogen in 1994 due to the established connection to gastric cancer. Eradication of *H. pylori* infections has become a standard treatment, yet the long-term consequences of eliminating *H. pylori* are not known. Indeed emerging evidence points to a protective role for *H. pylori* in gastroesophageal, pulmonary, and metabolic diseases. Thus *H. pylori* research now takes an unexpected turn where its potential benefits for the human host are investigated. The outcome will determine whether we need to reassess our relationship to *H. pylori* and the relative benefit of eradication.

Microbiology and Genome

Genus *Helicobacter* comprises >35 species; many of them non-culturable. *H. pylori* is the major medically relevant pathogen, but other species have been detected in human clinical samples. Non-*Helicobacter pylori* *Helicobacter* (NHPH) of human or animal origin have drawn recent attention due to their possible involvement in inflammatory bowel disease (IBD) and importance in animal health. Gastric and enterohepatic NHPH isolated from humans include *H. hepaticus*, as well as *H. cinaedi*, and *H. suis*, which pose risk for immunocompromised patients. *H. felis*, *H. bizzozeronii* and *H. salomonis* have been associated with chronic gastritis and peptic ulcers in humans. Strains of *H. hepaticus*, *H. bilis* and *H. mustalae* show carcinogenic potential in animals. Well-characterized strains of *H. felis*, *H. mustalae*, and *H. hepaticus* are finding use in gastric mouse colonization models.

H. pylori belongs to the epsilon subdivision of proteobacteria. The bacterium has been (re)named many times beginning with *Vibrio rugula*, then *Campylobacter*-Like Organism (CLO), *Campylobacter pylroidis*, and subsequently *C. pylori* until the new genus *Helicobacter* was established in 1989. It is a spiral shaped, highly motile bacterium with a unipolar bundle of 2–6 flagella. Production of catalase, oxidase and particularly urease enables the organism to persistently colonize the human gastric mucosa. Urease activity neutralizes gastric acidity by generating ammonium from urea. Optimal growth of *H. pylori* in vitro requires rich media supplemented with blood, serum, or cyclodextrin, 37°C and a microaerobic (5% oxygen) atmosphere. Colonies become visible after 2–10 days of incubation. Isolation and cultivation of *H. pylori* from gastric biopsies is still challenging due to their fastidious ex-vivo growth behavior. Selection medium for *H. pylori* ideally contains vancomycin, trimethoprim, cefsulodin, and amphotericin B. Incubation of biopsies with trypsin prior to plating can facilitate *H. pylori* isolation. The bacterium's morphology can change from spiral shaped (gastric biopsies) to rod-like (cultivation plates) and finally coccoidal cells, which are viable but not culturable. Alterations are detected after prolonged incubation on plates, or exposure to subinhibitory concentrations of certain antibiotics or other hostile conditions. The coccoid forms (found also in stomach biopsies) have not been linked to virulence but strong evidence indicates that these represent persister cells, able to subvert treatment, the immune system, and allow environmental passage.

The first whole genome sequence of *H. pylori* (strain 26695) was released in 1997. A 5,300-year-old *H. pylori* genome could be retrieved from human remains preserved in glacier ice and made available in 2016. In total NCBI currently lists 577 genome reports for *H. pylori*, 84 of them are finished sequences and plasmids are frequent. Genome properties are very constant with an average genome size of about 1.6 kbp, an average GC content of 39%, and approximately 1,500–1,600 predicted coding sequences per strain. Depending on the methods and strain pool analysed, the core genome is calculated with 1,063–1,300 genes and the pan-genome with 2,070, which, however is considered "open" and may extend to 5,000 genes. Data from transcriptome, methylome, and proteome analyses have provided important insights to gene regulation and virulence properties of *H. pylori*. The *H. pylori* genome is highly methylated and exhibits strain-specific variation. *H. pylori* possesses an unusually high number of restriction modification (R-M) systems of all four types. Generally, methylation of recognition site prevents DNA cleavage. Some of the R-M systems are subject to phase variation. Analysis of the primary transcriptome revealed an unexpected complexity in the gene regulation of *H. pylori*. Many transcriptional start sites were located within operons and opposite to annotated genes signifying uncoupling of polycistrons and antisense transcription. *H. pylori* encodes more than 60 small RNAs including the 6S RNA previously thought to be absent. Small RNAs are important mediators of post-transcriptional regulation under stress and during virulence. The data also underlines the complexity of the fairly small genome of this highly adapted mucosal colonizer.

[☆]Change History: February 2017. Sabine Kienesberger and Ellen L. Zechner verified the proofs. No major changes were made.

This article is a reprint of Sabine Kienesberger, Ellen L. Zechner, *Helicobacter pylori*, Reference Module in Biomedical Sciences, Elsevier, 2017.

Population Genetics and Evolution

H. pylori is cohabitating with humans probably since the early development period of the genus *Homo* but definitely predating the human migration out of Africa (approx. 60,000 years ago). The phylogeographic structure of *H. pylori* is a result of coevolution with humans and immensely valuable to study migration of prehistoric and recent populations. Currently, 7 ancestral *H. pylori* populations and 14 subpopulations are described. Human genetic diversity decreases with distance from East Africa and *H. pylori* parallels this, indicating a close association and co-evolution. In general, strains from family members are highly similar and strains isolated from unrelated persons show extensive differences in nucleotide sequence and gene content. It is also apparent that one person can be colonized by multiple *H. pylori* strains. Mixed infections of one stomach are major drivers of allelic diversification due to intra- and inter-strain recombination events and gene shuffling. Horizontal gene transfer contributes substantially to *H. pylori* evolution. The bacterium is naturally competent for DNA uptake via transformation and it frequently carries conjugative plasmids and transferable chromosomal elements. Slip strand mispairing at dinucleotide repeats and homopolymeric tracts affects protein expression generally and has been described for genes encoding surface structures like lipopolysaccharide (LPS). During infection *H. pylori* experiences multiple types of DNA damage and in contrast to earlier contentions, several DNA repair pathways are available to promote survival in the acidic gastric niche. The mutation rate in *H. pylori* is high and most genes are under negative selection. Notably, however, several genes encoding surface structures and the virulence factor cytotoxin-associated gene A (CagA) are under diversifying selection, which allows adaption to the host and persistence by immune evasion.

Epidemiology and Transmission

50% of the world's human population is infected. Current major determinants of prevalence are socioeconomic conditions and age. Improved hygiene and use of antibiotics has brought about rapidly declining colonization rates in industrialized countries that can be as low as 10% compared to 90% in developing countries. In high-risk areas (developing countries) and high-risk populations (i.e. indigenous) almost everyone acquires *H. pylori* by age 5, whereas in developed countries the overall prevalence is 40–60%. Frequency of *H. pylori* is equal in women and men. The infectious dose of *H. pylori* is unknown but there is strong evidence for fecal-oral, oral-oral, and vomituous-oral routes of acquisition. Contaminated water is a probable risk factor but possibly can be neglected as an important route since transmission within family members (mainly mothers to children) is well established and also occurs within communities where people live in close contact.

Pathogenesis

Research with this pathogen over nearly four decades has applied in vitro experiments as well as animal models (mice, Mongolian gerbils and rhesus macaques). Despite many gaps in knowledge and difficult challenges, detailed understanding of *H. pylori* pathogenesis mechanisms and its interaction with the immune system is emerging. Successful colonization, persistent infection, and onset of disease pathogenesis are accomplished in several steps. The bacterium's corkscrew shape and flagellar movement allow it to efficiently swim from the lumen to the epithelium and penetrate the thick, viscous layer of mucus to initiate colonization of the stomach. Production of urease helps to neutralize gastric acidity and lower viscosity of the mucus. The mucus-associated bacteria then become cell-associated to avoid displacement from the stomach by peristalsis and gastric emptying. Intracellular *H. pylori* have been observed in vitro (cell culture) and in vivo (biopsies) although at low frequencies. *H. pylori* stimulates gastric epithelial cells and thus induces an innate response characterized by the production of chemokines, which leads to the recruitment of myeloid cells, including macrophages, in the gastric mucosa. The pathogenesis of *H. pylori*-induced diseases is mediated by the infiltration, activation, and persistence of cells of the innate and chronic immune response. A sophisticated adaptation to the immune response is key to persistent colonization.

Immune Responses, Immune Evasion, and Host Factors

H. pylori interferes with many immunological pathways and disease outcome is strongly dependent on how and at which state host immune cells are manipulated. The interaction is very dynamic over time and many immunological pathways and cascades are constantly stimulated by the bacterium. Successful chronic colonization and bacterial persistence depends on multiple factors and the bacterium has developed a wide repertoire of strategies to evade host defenses.

When *H. pylori* enters the stomach it immediately interferes with the host's non-specific defense program against pathogens and the innate immune response. *H. pylori* swims through the mucus towards the epithelial cells where adherence, invasion and toxin release leads to disruption of tight junctions, altered cell polarity, cytoskeletal rearrangements and induction of apoptosis. Adhesins, urease, CagA and VacA are key manipulators of gastric epithelial cells, which react by activation of NFκB, cytokine release (Interleukin (IL)-10, IL-8, IL-6, IL-1β), followed by infiltration of immune cells including macrophages and dendritic cells (DC) towards the injured tissue. IL-10 is an immune suppressant important for chronic colonization and levels of cytokines vary depending on the state of infection (acute or chronic).

In epithelial cells and incoming macrophages, urease secreted by *H. pylori*, but not LPS, triggers the production of nitric oxide (NO), a free radical synthesized by the enzyme NO synthase (NOS) through the oxidation of L-arginine. In contrast to many enteropathogens *H. pylori* is less well equipped to resist direct effects of oxidative and nitrosative stress. Nonetheless, *H. pylori* successfully counters the deleterious effects of NO by expressing protective reductases, by L-arginine depletion of the extracellular milieu and most importantly, by blocking host NO production through transcriptional and translational CagA dependent down-regulation of NOS2 expression.

Macrophages and DCs typically express toll-like receptors (TLR) on the surface. An important evasion strategy of *H. pylori* is to avoid recognition by TLR. *H. pylori* flagellin is not recognized by TLR5 and, in contrast to other bacteria, CD14 and TLR4 poorly recognize *H. pylori* LPS. Phase variation in the Lewis antigens (see below) allows efficient evasion by minimizing the activation of cascades such as the complement pathways necessary for pathogen clearance. Moreover, *H. pylori* can prevent phagocytic killing in a CagA- and VacA-dependent manner and can induce apoptosis of macrophages. However, if macrophages are activated they produce IL-6, IL-1 β , IL-12 and TNF α , which help to initiate a Th1 type response.

T-cells and DCs play an important role in immune recognition and response to *H. pylori*. The urease subunit B (UreB) together with LPS activates the NLRP3 inflammasome in DCs via MyD88, NF- κ B, TLR4 (LPS), and TLR2 (UreB) leading to caspase 1 activation and secretion of cytokines IL-1 β and IL-18. IL-1 β drives Th1 or Th17 differentiation, whereas IL-18 allows T regulatory (Treg) cell differentiation (CD4⁺ CD25^{hi}). Thus, the T-cell response invoked varies between immune tolerance (Treg)—resulting in reduced disease incidence and probably to life-long bacterial persistence – and infection control (Th1/Th17). The latter leads to increased gastric inflammation, tissue injury and disease induction. Asymptomatic carriers generate *H. pylori* specific Tregs and patients with peptic ulcers display a pathogenic T-cell response. The interaction of *H. pylori* with DCs is a key factor in persistent colonization since *H. pylori* exposed “tolerogenic” DCs fail to induce a Th1/Th17 response but convert naïve T-cells into Tregs in a contact-dependent way directing the T-cell response away from the pathogenic response.

In chronic human colonization, macrophages, neutrophils, DC, mast, B-cells and a higher count of CD4⁺ T-cells compared to CD8⁺ T-cells are usually present. The existing CD4⁺ T-cells are typically Treg cells, which suppress both innate and adaptive immune responses and suppress the induction and proliferation of effector T-cells. Moreover, numerous cytokines, including gamma interferon (IFN- γ), tumor necrosis factor (TNF), IL-1 β , IL-6, IL-7, IL-8, IL-10, and IL-18, are elevated in the stomachs of *H. pylori*-colonized humans compared to uninfected humans.

In terms of the humoral immune response it is notable that *H. pylori* induces a strong B-cell response and colonized patients normally display a classical and long-lasting immunoglobulin- (Ig) A, IgM and IgG titer. Immunodominant factors are UreB, CagA, and VacA. However, this response is not sufficient to clear infection. In contrast, the induction of autoantibodies by *H. pylori* might be counterproductive and influences disease.

Generally, the immune response eclipsed by *H. pylori* is dependent on host factors like genetic background and age, and on the genetic versatility of the colonizing strain. Also environmental factors like smoking, food and high salt intake or dietary antioxidants play an important role. To add complexity, mouse studies showed that colonization not only interferes with immune cells in the stomach but also impacts immunity in distal tissue like the lung and the microbiota, which is linked to immune development.

The response to *H. pylori* is versatile and since so many host pathways and genes are affected, it is not surprising that host genetics are directly linked to disease outcome. Inter-individual variations in cytokine response due to polymorphisms are particularly important contributors to the diversity of clinical outcomes. Higher risks for gastric cancer in many populations were reported to be due to differences in genes coding for IL-1 β , TNF α , IL-8, IL-10, and IL-18, as well as variations in their receptor antagonists. Moreover, polymorphisms in genes of the TLR signaling pathways influence the risk of gastric cancer.

Host Interaction (Virulence) Factors

Adhesion

Once *H. pylori* reaches the epithelial cell layer, adhesion is crucial to avoid shedding and to allow directed manipulation of host cells. *H. pylori* have >30 genes encoding *Helicobacter* outer membrane porins (Hop) and related adhesins. The blood-antigen binding protein A (BabA) and the sialic acid-binding adhesin (SabA) are most crucial for cell attachment. BabA binds to the ABO/Lewis^b antigen exposed on the surface of the gastrointestinal mucosal epithelial cells and red blood cells. SabA binds to sialylated and sulfated glycans. The inflammatory response induced during infection results in up-regulation of these negatively charged glycans and reinforces bacterial attachment to host cells. Components of the *cag*-encoded pilus interact with integrins (described below). Recent work has identified a key interaction between the surface exposed adhesion HopQ and human apical carcinoembryonic antigen-related cell adhesion molecules (CEACAMs) that is glycan independent. The purpose of this interaction is not yet clear, but lack of *hopQ* disrupts T4SS mediated delivery of CagA.

cag Pathogenicity Island and the Cytotoxin Associated Gene A (CagA) Protein

H. pylori appears to have acquired the *cag*-pathogenicity island (*cag*) via horizontal gene transfer and the island has been steadily maintained in virulent strains. Presence of *cag* is a major determinant of disease outcome due to expression of the CagA protein, which is able to interact with a wide range of host signaling proteins and undergo tyrosine phosphorylation modifications. CagA is delivered directly into the cytoplasm of the gastric epithelium and immune cells by a multicomponent bacterial type IV secretion

system (T4SS) that spans both bacterial and host cell membranes. The protein components required for secretion are encoded together with *cagA* on the pathogenicity island. These genes can be upregulated in vitro by acidic or high salt conditions and upon contact with epithelial cells. Their expression in vivo was confirmed in animal models. The T4SS forms an extracellular pilus, establishes contact with the host cell via integrin receptors and delivers the multifunctional CagA effector protein. Phosphorylation of CagA by c-SRC and c-ABL family kinases on the protein's Glu-Pro-Ile-Tyr-Ala (EPIYA) motif occurs after translocation. Both CagA and its phosphorylated forms interact with multiple host proteins resulting in broad dysregulation of cell signal transmission and cellular processes.

The *cag* T4SS and CagA activate transcription factor NF- κ B via multiple pathways resulting in increased expression and release of proinflammatory IL-8 to the gastric lumen, as well as enhanced expression of other cytokines, enzymes, regulatory factors and angiogenic factors ultimately causing chronic gastric inflammation. CagA phosphorylation independent signaling alters epithelial cell to cell junctions by interaction with junctional adhesion molecules, zonula occludens, PAR1 and E-cadherin. CagA activity also causes loss of cell polarity, cytoskeletal rearrangements and formation of elongated cells characteristic of the *hummingbird* phenotype. Activation of the ERK pathway is a phosphorylation independent activity of CagA resulting in increased proliferation of epithelial cells.

Substantial research in recent years has been committed to understanding the mechanistic basis of pathogen-induced disease and the significance of *cag* using in vitro systems and experimental infection models in mice and Mongolian gerbils. CagA is not essential for stomach colonization and strains often lose their ability to translocate CagA during mouse colonization studies. Comparison of infection by *cag* + and *cag* deficient *H. pylori* strains in Mongolian gerbils clearly link CagA to expansion of gastric adenocarcinoma, and in transgenic animals (mouse, zebrafish, *Drosophila*) expressing CagA systemically, elevated JNK activation and Wnt target-gene upregulation resulted in intestinal cell proliferation, adenocarcinoma and small cell carcinoma. The sum of data clearly demonstrates CagA's cancer-promoting capability, allowing CagA to be identified as the first bacterial oncoprotein. The majority (60–70%) of Western *H. pylori* strains and almost 100% of East Asian strains express CagA.

Vacuolating Cytotoxin A (VacA)

Secretion of the pore-forming toxin VacA supports persistence and survival of *H. pylori* in the human stomach. The *vacA* gene is present as a single chromosomal copy in all *H. pylori* strains, yet mosaicism is common. Distinct *vacA* alleles encode toxin molecules with different activity and receptor affinity. The 140 kDa protoxin is processed to a 88 kDa monomer for secretion. Activation of the toxin requires acid exposure and oligomerization. VacA targets primarily gastric epithelial cells yet translocation of the bacterium to the lamina propria exposes immune and parietal cells to VacA as well. In vitro, VacA disrupts epithelial barrier function and endosomal compartments allowing toxin-dependent ion influx and formation of acidic intracellular vacuoles. VacA unleashes multiple cellular effects. Access to immune cells supports its immunosuppressive phenotype. Interaction with dendritic cells promotes immune tolerance. Moreover, VacA interferes with T cell proliferation as well as IL-2 production and secretion.

Colonization Factors

Motility and Chemotaxis

Efficient motility is essential for persistent colonization of the gastric mucus layer. *H. pylori* is highly motile compared to other bacteria and strains exhibit different numbers of flagella of varying lengths. A higher degree of flagellation correlates with increased swimming speed. More than 40 proteins are involved in the biosynthesis and operation of the polar, sheathed flagella. Conserved *fla*, *fli*, and *mot* genes are sequentially expressed and subject to complex regulation on multiple levels including transcriptional, posttranscriptional, posttranslational mechanisms and phase variation. The flagellum is divided into the hook-basal body (HBB) complex and the extracellular filament. The HBB spans from the cytoplasm to the surface-localized hook. The inner part of the HBB is comprised of a functional type III secretion system that secretes many components of the flagellum and other proteins. MotA and MotB form the stator complex and the higher than average number of stator units present in *H. pylori* might generate higher torque and efficient motility. *H. pylori* senses and responds to chemical cues. Flagellar rotation can turn clock- or counterclockwise in response to chemosensory directed signals. In the stomach the bacterium prefers to swim towards injured tissue. The three membrane-bound chemoreceptors TlpABC and the cytoplasmic sensor TlpD sense different environmental conditions and interact with the Che-system. CheW, CheA, and CheY form the core-signaling complex and interact with the flagellar motor to control the direction of rotation. Mutants in the chemotaxis system are less virulent and in total up to 100 genes contribute to forming a chemoresponsive flagellum. As a final note, part of the capacity of *H. pylori* to escape detection is that flagellin is not recognized by TLR5, and thus fails to induce nuclear factor (NF)- κ B. Moreover, flagellin fails to induce IL-8 production in gastric epithelial cells.

Urease Activity

H. pylori is a neutrophile that survives stomach acid using a urease-based acclimation mechanism. The enzyme hydrolyzes urea to produce ammonia, which is released to the cytoplasm and periplasm, neutralizing the local pH. The urease gene cluster comprises 7 genes where *ureA* and *ureB* encode catalytic subunits and *ureE-H* specify accessory proteins important to chaperoned assembly of the apoenzyme and nickel cofactor. Intrabacterial urease activity is regulated by a proton-gated channel UreI, which imports urea under

acidic conditions. Cytoplasmic urease prevents collapse of the transmembrane potential difference by maintenance of a constant internal and periplasmic pH. Surface bound urease increases the pH of the local extracellular milieu. Uptake and homeostasis of the metal cofactor nickel is well regulated. Transcription of *ureA* and *ureB* is controlled by NikR, a common regulator of nickel-dependent enzymes. Nickel uptake is governed by NixA and an ABC transporter. *H. pylori* has an elaborate system to store nickel via Ni²⁺ binding proteins Hpn and HpnI and further regulates nickel homeostasis via chaperonin HspA (GroES). A succession of transfer reactions passages the metal from Hpn and HpnI to higher affinity binding proteins like HypA and HypB, which then transfer the metal to the urease apoenzyme. Urease production is not only important for colonization, it also leads to tissue injury by provoking the NO response, manipulates immune cells and modulates phagosome pH to support *H. pylori* survival within macrophages.

LPS and Lewis Antigens

Lipopolysaccharide (LPS) is the main outer membrane component of Gram-negative bacteria and the LPS presented by pathogens usually has strong immunostimulatory and inflammatory capacities. It is composed of the endotoxic lipid A, the core oligosaccharide, and the O-antigen. To evade the innate immune response, *H. pylori* masks the negative charges on its lipid A and removes phosphate groups from the backbone to avoid binding by cationic antimicrobial peptides (CAMPs) and activation of hTLR4-MD2. Moreover, *H. pylori* LPS poorly binds to CD14 and TLR4 thus macrophage activation is avoided. *H. pylori* also promotes immune evasion and chronic infection by host mimicry of Lewis (Le) antigens expressed by gastric epithelial cells. The O-antigen of *H. pylori* is decorated by two types, Le^{a/b} (type I) and Le^{x/y} (type II), to avoid host recognition. Finally, phase variation of the Le antigens contributes to the heterogeneity of *H. pylori* LPS and immune tolerance.

Diseases Associated With *H. pylori*

Host Response to *H. pylori*

Initial infection by *H. pylori* usually remains unnoticed and is rarely diagnosed. In some cases colonization triggers nondiagnostic symptoms such as dyspepsia, abdominal cramps and vomiting. Gastritis is the inflammation of the inner lining of the stomach and follows mucosal injury. The acute ("active") inflammation is associated with neutrophilic infiltration, while the chronic inflammation is characterized by the presence of mononuclear cells, primarily lymphocytes, plasma cells and macrophages. Colonization with *H. pylori* classically results in a response of the gastric tissue that is termed chronic active gastritis. This inflammatory response is absent in *H. pylori*-free persons. A valid point increasingly debated, however, asks which situation should be considered as "normal" – the presence of an organism that has coevolved with humans from the beginning of mankind, or its absence? It is important to keep in mind that the inflammatory response to *H. pylori* might be beneficial in the stimulation and education of our immune system. The host response varies in its intensity and anatomic distribution and is dependent on the colonizing strain as well as on host genetic susceptibility and environmental factors. Only an excessive inflammatory response drives pathological processes in the gastric epithelium heightening risk for symptomatic gastritis, ulcer disease or cancer but importantly, 80–90% of infected individuals remain asymptomatic throughout their lifetime.

Ulcer Disease

Peptic ulcer disease (PUD) refers to painful sores that develop in the lining of the stomach, lower esophagus, or small intestine. Only ~10% of chronically infected patients, particularly those that manifest increased acid secretion, are predisposed to develop peptic ulcer disease. *H. pylori* has clearly been linked to duodenal ulcers since elimination of *H. pylori* substantially reduces ulcer relapses. Moreover, the incidence of PUD has declined as *H. pylori* disappears from human populations. Studies in Asian populations correlate diminished *H. pylori* prevalence and reduced occurrence of duodenal ulcers from 21.1% to 5.0% and that of gastric ulcers from 11.9% to 9.9% within 20 years. For appropriate management of patients with gastric ulcers, medication (non-steroid anti-inflammatory drugs (NSAIDs)) might be more important than *H. pylori*, as NSAID in combination with *H. pylori* colonization increases the risk of peptic ulcer bleeding. Generally, this underscores the recommendation is to eliminate *H. pylori* in all patients with ulcer disease.

Gastric Carcinoma

The most common cancer of the stomach is adenocarcinoma (neoplasia of epithelial tissue with glandular origin). Gastric adenocarcinoma is the third leading cause of cancer-related deaths in the world. Chronic inflammation induced by long term colonization with *H. pylori* is a major risk factor leading to the induction of stem cell hyperplasia, morphological changes in gastric mucosa and gastric cancer development. 1 to 3% of persons colonized with *H. pylori* develop gastric adenocarcinoma and the outcome is often poor with a less than 10% 5-year survival rate globally. Infection, inflammation, and antitumor immunity are key elements of disease progression. Factors like colonizing strain, host genetics (e.g. increased NOS2 gene expression and polymorphism in modulatory cytokines or TLR related genes), host microbiota, as well as environmental influences including diet, play a role in the pathologic outcome of *H. pylori* colonization.

Gastric Lymphoma

The stomach is the most frequent site of extranodal lymphoma. Gastric lymphoma originating from mucosa-associated lymphoid tissue (MALT) typically originates from B-cells in the marginal zone of the MALT. These non-Hodgkins's lymphomas (NHL) (no Reed-Sternberg cells) are relatively rare, that is 2-3% of all malignancies in the world are NHL and MALT lymphomas comprise approximately 5% of all NHLs. These malignancies are associated with chronic inflammation and the development of lymphoid follicles in the submucosa due to *H. pylori* colonization. *H. pylori* infection protects splenic B-cells from apoptosis possibly having consequences for the lymphoma. *H. pylori* eradication may induce tumor remissions and important factors in response to *H. pylori* eradication therapy are tumor stage, depth of invasion, and localization, as well as geographic region. *H. pylori* is also linked to diffuse large B-cell lymphoma (DLBCL) with and without signs of MALT. Pure DLBCL (no signs of MALT) is normally treated with systemic chemotherapy however, full pathologic remission has been documented after *H. pylori* eradication therapy in *H. pylori*-positive pure DLBCL and DLBCL(MALT).

Extra Gastric Disease and Potential Benefits

H. pylori leads to infiltration of immune cells in the stomach, affects distal immune responses, and there is also evidence that the presence of *H. pylori* influences the gastric and intestinal microbiome, thus it is conceivable that *H. pylori* may variably cause, influence or protect from extra gastric disease. Currently, it is controversially reported and discussed whether *H. pylori* can induce or negatively influence cardiovascular and neurologic disorders, or influence dermatologic disorders, head and neck disease, or complications during pregnancy, as well as diabetes mellitus. A link has been established between *H. pylori* infection and a negative impact on idiopathic thrombocytopenic purpura, sideropenic anemia, and vitamin B12 deficiency. By contrast evidence indicates that *H. pylori* has a protective role in the development of early onset asthma (see below). Moreover, early childhood exposure to *H. pylori* might protect from gastroesophageal reflux disease (GERD) and Barrett's esophagus, allergic rhinitis, eczema, skin sensitization, and inflammatory bowel diseases. The current status of research clearly demands further studies given the high impact of these diseases on public health.

Treatment, Antibiotic Resistance and Vaccine Development

Current guidelines suggest that the decision to test for *H. pylori* should be made with therapeutic intent, thus *H. pylori* should be eradicated if detected. Despite susceptibility to many antibiotics in vitro, no single agent achieves eradication rates above 55%. Efficacy is improved with acid suppression; therefore the standard triple therapy combines proton-pump inhibitors (PPI) and two antibiotics. Antimicrobial eradication levels are decreasing (as low as 60%) and are inversely correlated with antibiotic resistance rates. First line therapy in regions with low clarithromycin resistance classically combines PPI, clarithromycin, and either amoxicillin or metronidazole for 14 days. In regions with high clarithromycin resistance failed eradication using second- and third-line therapies may require cultivation of *H. pylori* and clarification of susceptibility. Regimes with the highest success rates include rifabutin, therefore this drug is best reserved as a third-line salvage therapy. Quadruple therapy with or without bismuth increases treatment success but new (non-antibiotic) strategies for eradication are clearly desired. So far, efforts to develop an effective vaccine were not successful. Several strategies triggering protective T cell-mediated immunity instead of humoral immunity have revealed useful antigens, adjuvants, and delivery routes, but effective protective immunity in humans was not achieved. Vaccine research is certain to continue. Nonetheless as our understanding of the beneficial functions of *H. pylori* also moves forward it may be prudent to reassess the value of eradicating human infection.

H. pylori and Asthma

Epidemiological studies in human populations have documented an inverse association of *H. pylori* colonization and the risk of developing allergic asthma, atopic rhinitis and other allergic diseases. These observations suggested that an exposure to *H. pylori* during childhood protects from diseases like early-onset asthma. In a comprehensive mouse asthma model, colonization of neonatal and adult mice confirmed the protective role of *H. pylori*, highlighting also the difference between early-in-life and late-in-life exposure to antigens. While adult mice develop chronic gastritis and preneoplastic lesions, mice infected early-in-life mimic the asymptomatic human carrier and are protected against gastric pathology. Neonatal mice develop a tolerance towards *H. pylori* that is characterized by the suppression of specific T-effector cells. VacA supports this response by blocking IL-2 production resulting in suppression of T-cell activation and proliferation (shown in humans). γ -glutamyl transpeptidase (GGT) prevents T-cells proliferation by arresting them in the G1 cell cycle phase. Moreover, both secreted factors indirectly prevent T-cell immunity by re-programming of DCs (only observed in mice). Exposure of DCs to *H. pylori* proteins forces these cells into a semi-mature state characterized by high levels of MHCII but low or no costimulatory molecules. These DCs produce IL-10 and IL-18 thereby supporting T-cell differentiation towards Treg cells while suppressing the development of Th1 and Th17 cells. As a side effect of this tolerogenic DC/Treg axis, protection against asthma is observed in the mouse model.

Conclusions

H. pylori is medically relevant and has become one of the most investigated bacteria world-wide. *H. pylori* can be genetically engineered, animal models are available and to some extent the bacterium can be studied in its natural niche—the human stomach. Co-evolution with the human host allowed *H. pylori* to acquire fascinating features. This organism is conceivably one of the best candidates we currently have to study and understand the dual (commensal/pathogen) role bacteria can establish with the human host. As such researchers in the field have recognized the opportunity to move beyond the singular view of negative consequences of infection to pursue the bigger picture. It follows that *H. pylori* research opens further opportunities to compare and relate these findings to other human colonizers, which might have a similar dual role in human health.

Glossary

Apoptosis The elimination of a cell through a process of programmed self-destruction, initiated by the binding of external mediators to the cell surface or disruption of normal metabolism.

Dendritic cells Cells of the immune system that specialize in taking up foreign material, processing it, and presenting it on their surfaces to lymphocytes, to initiate an antigen-specific immune response.

Disseminated intravascular coagulation A hemorrhagic syndrome that results from extensive activation of the coagulation system, with consumption of coagulation factors and platelets and production of fibrin degradation products.

Endothelium The layer of cells that lines the inner surface of blood and lymphatic vessels.

Inflammation The complex of changes that occur in a tissue and its blood vessels in response to an injury or microbial invasion, stimulated by products released by macrophages and other cells, which result in increased blood flow, transudation of proteins, and an influx of cells capable of attacking microorganisms.

Interferons A class of proteins produced by several cell types in response to viral infection that induce a battery of intracellular countermeasures against viral replication.

Macrophages Cells derived from precursors in the bone marrow, which are widely distributed throughout the tissues of the body, which ingest and destroy microbes and induce inflammatory changes through the release of mediators.

Zoonosis An infection shared by humans and animals; the term is usually applied to situations in which the animal host maintains the infectious agent while showing little sign of disease.

Defining Statement

The hemorrhagic fever viruses are a group of RNA viruses that are maintained in animals and/or arthropod vectors, but cause severe illness in humans characterized by coagulation defects, increased vascular permeability, and shock. They share the ability to replicate in macrophages, suppress interferon responses, and induce a massive release of proinflammatory mediators.

Introduction

The hemorrhagic fever viruses are members of four different RNA viral families that cause a disease in humans characterized by coagulation defects that can result in bleeding and increased vascular permeability that can lead to a fall in blood pressure, shock, and death. The term 'viral hemorrhagic fever' was first used in the early 1950s to designate an illness that occurred sporadically among soldiers fighting in the Korean War, which is now known to result from exposure to the excretions of local rodents chronically infected by a hantavirus. Over subsequent decades, some 15 additional viral infections, ranging from the ancient plague of yellow fever to the highly lethal disease caused by the newly discovered microbes, Marburg and Ebola virus, have been found to meet the criteria for the hemorrhagic fever syndrome (Table 1).

[☆]*Change History:* September 2014: M Holbrook and M Bray updated the entire article with addition of Alkhurma and Lujo viruses to the text and a separate section for vaccines.

This article is an update of S. Suerbaum, M.J. Blaser, *Helicobacter pylori*, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 163–169.

Table 1 Taxonomic classification, geographic distribution, natural reservoirs, and vectors of the causative agents of viral hemorrhagic fever

<i>Virus</i>	<i>Disease</i>	<i>Geographic distribution</i>	<i>Reservoir host</i>	<i>Arthropod vector</i>
<i>Arenaviridae</i>				
Lassa virus	Lassa fever	West Africa	Rodents	None
Lujo virus	Lujo HF	Southern Africa	Unknown	Unknown
Junin virus	Argentine HF	Argentina	Rodents	None
Machupo virus	Bolivian HF	Bolivia	Rodents	None
Guanarito virus	Venezuelan HF	Venezuela	Rodents	None
Sabia virus	Sabia HF	Brazil	Rodents	None
Whitewater Arroyo virus	Whitewater Arroyo HF	California, USA	Rodents	None
<i>Bunyaviridae</i>				
Crimean-Congo HF virus	Crimean-Congo HF	Southern Eurasia, Balkans, Africa	Hares, birds, livestock	Ticks
Rift Valley fever virus	Rift Valley fever	Sub-Saharan Africa	Livestock, unknown	<i>Culex</i> , <i>Aedes</i> mosquitoes
Hantaviruses (Old World)	HF with renal syndrome	Northern Eurasia, China, Korea	Rodents	None
Hantaviruses (New World)	Hantavirus pulmonary syndrome	North and South America	Rodents	None
<i>Filoviridae</i>				
Ebolavirus	Ebola HF	West Africa	Unknown	Unknown
Marburgvirus	Marburg HF	Africa	Unknown	Unknown
<i>Flaviviridae</i>				
Yellow fever virus	Yellow fever (urban)	Africa, South American cities	Humans	<i>Aedes aegypti</i> mosquitoes
	Yellow fever (sylvan)	Africa, South American forests	Monkeys	<i>Haemagogus</i> , <i>Aedes</i> mosquitoes
Dengue virus	Dengue fever, dengue HF	Tropics worldwide	Humans	<i>Aedes aegypti</i> mosquitoes
Kyasanur Forest disease virus	Kyasanur Forest disease	Mysore State, India	Monkeys, rodents, birds	<i>Haemaphysalis</i> ticks
Alkhurma virus	Alkhurma HF	Saudi Arabia, Southern Egypt	Unknown	<i>Ornithodoros</i> ticks, other?
Omsk HF virus	Omsk HF	Russia	Rodents, muskrats	<i>Dermacentor</i> ticks

All of the hemorrhagic fever viruses have single-stranded RNA genomes, which differ in the polarity of the genome and in the number of segments into which it is divided (positive-sense, one segment for the flaviviruses; negative-sense, one segment for the filoviruses; negative-sense, two segments for the arenaviruses; and negative-sense, three segments for the bunyaviruses). They also differ in morphology: The arena-, bunya-, and flaviviruses are spherical, while the filoviruses are long and filamentous. All of the hemorrhagic fever viruses are 'enveloped' – that is, their surface glycoprotein molecules are anchored in a lipid bilayer derived from host cell membranes.

Almost all types of viral hemorrhagic fever are 'zoonoses': their causative agents infect various animal species, but can be transferred to humans through direct contact with an animal, exposure to its excretions, or the bite of a blood-feeding arthropod. The geographic distribution of each disease therefore corresponds to the range of the host species or arthropod vector. Because these viruses have no history of adaptation to humans, they have not acquired efficient mechanisms of person-to-person transmission. Spread of infection therefore either does not take place at all, or requires direct contact with virus-containing body fluids. In endemic areas, these diseases tend to occur either as single cases or as small clusters of infections that quickly 'burn out'. Dengue virus is not a zoonotic virus as it has adapted to a cycle of person-to-person transmission by blood-feeding mosquitoes that enables them to persist among human populations without the support of an animal reservoir. Yellow fever virus has also adapted to mosquito-driven person-to-person transmission in urban settings, but maintains a zoonotic transmission cycle in jungle settings where non-human primates serve as the reservoir host.

Because viral hemorrhagic fever occurs almost exclusively in regions of the world that lack a medical research infrastructure, few data on the pathogenesis of these diseases have been obtained by studying sick people. Instead, most of the current knowledge of the underlying mechanisms of illness has been obtained from experiments on laboratory animals. As discussed later under 'Pathogenesis of viral hemorrhagic fever', this article shows that despite differences in their basic replication strategy, geographic distribution, and the identity of their maintenance hosts, the hemorrhagic fever viruses appear to interact with the human immune system in a similar manner. All of them replicate in monocytes and macrophages, and they also infect dendritic cells, which have primary responsibility for initiating an adaptive immune response by presenting antigens to lymphocytes. Suppression of type I interferon responses permits rapid virus dissemination, and the release of large quantities of proinflammatory mediators plays a critical role in the development of the major signs and symptoms of illness.

Clinical Features and Laboratory Tests

All types of viral hemorrhagic fever can be associated with a significant case-fatality rate, but they differ in average severity. For example, roughly 5% of cases of dengue hemorrhagic fever end in death, but mortality in large outbreaks of Ebolavirus

and Marburgvirus infections in Africa has ranged from 50% to 90%. Because these diseases resemble each other in their clinical presentation and in the results of standard laboratory tests, a specific diagnosis requires the performance of specialized assays.

Signs and Symptoms

Viral hemorrhagic fever usually begins with the abrupt onset of fever and malaise, accompanied by headache, muscle and joint pain, nausea, vomiting, abdominal pain, and diarrhea. The vasodilatation and diffuse 'vascular leak' that are the major physiologic abnormalities leading to shock sometimes produce cutaneous flushing and soft tissue edema, but are manifested most clearly through a fall in blood pressure. Coagulation defects may cause the development of a maculopapular rash, petichiae, ecchymosis prolonged bleeding from needle puncture sites, conjunctival hemorrhages, and easy bruising. Major hemorrhage from the gastrointestinal and urinary tracts is generally seen only in severely ill patients, as a terminal phenomenon.

Despite the syndrome's name, bleeding is rarely the cause of death. Instead, the life-threatening lesion is a profound alteration of vascular function induced by high circulating levels of proinflammatory mediators, which combines the diffuse dilatation of small vessels with the increased permeability of their endothelial linings, permitting fluid and proteins to move out of the plasma into the interstitial space. The resulting reduction in effective blood volume produces circulatory insufficiency, stupor, coma, multiorgan failure, shock, and death (see 'Pathogenesis of viral hemorrhagic fever'). For most types of viral hemorrhagic fever, changes in neurologic function reflect a decrease in circulatory perfusion, rather than viral invasion of the central nervous system, so they resolve as the patient recovers.

Findings in Standard Laboratory Tests

The numerous physiologic changes induced by host responses to infection produce a wide range of abnormalities on standard laboratory tests. Increased vascular permeability results in diminished plasma volume, which is reflected in a rising hemoglobin concentration and hematocrit in the complete blood count and in a fall in albumin concentration, while the total protein may remain normal. Diminished circulatory volume also impairs renal function, as manifested by rising urea nitrogen and creatinine levels. As regards the complete blood count, high levels of circulating chemokines evoke the release of leukocytes from the bone marrow, producing an increased percentage of immature granulocytes in blood smears. At the same time, the lymphocyte count may fall as a result of the loss of these cells through apoptosis over the course of infection (see 'Pathogenesis of viral hemorrhagic fever').

For most viral hemorrhagic fevers, the shift to a procoagulant state that accompanies systemic inflammation also leads to a consumption of coagulation factors, which will eventually be manifested in a prolongation of the prothrombin and partial thromboplastin times and a fall in the platelet count. As the patient's condition worsens, fibrin split products and D-dimers will appear in the plasma, consistent with disseminated intravascular coagulation. The spread of infection to hepatic parenchymal cells is reflected in the appearance of elevated levels of liver-associated enzymes, such as aspartate and alanine aminotransferase, in the plasma, and may also contribute to deficits in coagulation factors.

Diagnosis

The physical findings and laboratory abnormalities described earlier are not unique to any one type of viral hemorrhagic fever, or even to the syndrome in general, but are also observed in many other infectious processes, including Gram-positive and Gram-negative bacterial sepsis, toxic shock, meningococcemia, plague, typhoid fever, leptospirosis, rickettsial infections, malaria, severe measles, and hemorrhagic smallpox. Making a firm diagnosis therefore requires the performance of specific microbiological and immunological procedures, such as antigen or antibody detection by enzyme-linked immunosorbent assay, identification of unique viral sequences by polymerase chain reaction, or the growth of the causative agent in cell culture. Because all types of viral hemorrhagic fever are characterized (from the earliest phase of illness) by the release of viral antigens and infectious virus from infected monocytes and macrophages into the plasma, blood is the most appropriate sample for testing.

Variation among Individual Types of Viral Hemorrhagic Fever

By definition, all types of viral hemorrhagic fever are characterized by fever, altered vascular function, and coagulation abnormalities, but individual agents also induce other physical changes that reflect specific virus–host interactions. For example, severe hepatic injury leading to jaundice is commonly seen in yellow fever (whence its name), but is rare or absent in the other syndromes. Some Rift Valley fever patients develop neurologic or ophthalmic complications that are not seen in the other diseases, while comparatively few develop hemorrhage. Lassa fever often shows an insidious onset and a lack of hemorrhagic complications. Renal insufficiency is characteristic of infection by the Old World hantaviruses, while the New World agents cause rapidly worsening cardiorespiratory failure, with the rapid onset of pulmonary edema. Despite the development of vascular leakage that leads to pulmonary edema, New World hantaviruses are not generally considered "true" hemorrhagic fever viruses.,

Pathogenesis of Viral Hemorrhagic Fever

As noted earlier, few data have been obtained from patients to elucidate underlying disease mechanisms. The only exception is dengue hemorrhagic fever, which has been studied in hospitalized patients in large tropical cities, but detailed research on the pathogenesis of the illness (and on that of the classic dengue) has still been hampered by the lack of good models of the disease in laboratory animals. At present, the most thoroughly studied form of viral hemorrhagic fever is the severe disease caused by the filoviruses, Ebola and Marburg, which has been studied to a limited extent in humans, but examined in great detail in laboratory animals, particularly non-human primates.

The fulminant illness caused by Zaire ebolavirus displays all of the classic features of the hemorrhagic fever syndrome. Exposure to the agent is usually followed within 3–7 days by the abrupt onset of high fever, malaise, and a variety of nonspecific signs and symptoms. These early changes are soon followed by a progressive fall in blood pressure, which in almost all cases leads to intractable shock and death. All patients show evidence of coagulation abnormalities, and bleeding from the gastrointestinal and genitourinary tracts is frequently seen during the terminal phase of the illness. Survival appears to require the rapid mobilization of a specific immune response: Those patients who develop anti-Ebola IgM or IgG antibodies during the second week of illness are likely to recover, while the persistence of high levels of circulating virus in the absence of a detectable antibody response is predictive of death.

Zaire ebolavirus is even more virulent for laboratory primates than for humans, causing uniformly fatal disease. The introduction of a few viral particles into a cynomolgus or rhesus macaque by injection, placement in the mouth or eye, or delivery as a small-particle aerosol initiates an inexorable process that appears to differ from the human illness only in that it proceeds more quickly and is uniformly fatal. Versions of the same virus that have been adapted to mice or guinea pigs through sequential animal-to-animal passage also cause a rapidly fatal illness that shares major signs and symptoms with the disease in humans and nonhuman primates. For the mouse-adapted variant, the lethal dose is a single virion.

Detailed time-course studies in these animal models have shown that four different mechanisms (discussed later in greater detail) act together to produce the clinical features of Ebola hemorrhagic fever (Figure 1). First, the virus replicates productively in

Figure. 1 Pathogenesis of filoviral hemorrhagic fever. Ebolavirus or Marburgvirus infection of macrophages leads to the generation of large numbers of new virions, release of proinflammatory mediators, and synthesis of cell-surface tissue factor. These agents also replicate in dendritic cells, impairing their ability to present antigens to the immune system. Suppression of type I interferon responses facilitates rapid viral dissemination. The direct effects of filoviral infection consist of the extensive tissue damage that results from the spread of virus to cells in the liver, adrenal glands, and other organs. Indirect effects include the induction of vasodilatation and increased vascular permeability by proinflammatory mediators and the massive apoptotic death of uninfected lymphocytes (see text).

monocytes and macrophages, inducing the release of large numbers of new virions and the production of proinflammatory mediators and tissue factor, which in turn cause vasodilatation, increased vascular permeability, and disseminated intravascular coagulation. Second, suppression of type I interferon responses by virus-encoded proteins supports the rapid dissemination of virus to monocytes, macrophages, and other cell types throughout the body. Third, the filoviruses are able to infect and kill a wide variety of parenchymal cells, resulting in extensive organ damage. Finally, the failure of adaptive immune responses, through the impaired function of virus-infected dendritic cells or macrophages and the massive destruction of lymphocytes through 'bystander' apoptosis, leads to a terminal state of 'immune paralysis' resembling that seen in septic shock.

Infection with filoviruses clearly results in the highest frequency of the most extreme form of the hemorrhagic fever syndrome, but it is reasonable to assume that the other types of viral hemorrhagic fever are produced by similar physiologic mechanisms. The following discussion of the four elements of pathogenesis is therefore based on the filovirus model, but also takes note of the extent to which the same phenomena have been identified in other diseases.

Proinflammatory Responses of Virus-Infected Macrophages

All of the hemorrhagic fever viruses make use of macrophages and their precursors, the monocytes, as their principal sites of replication. These ubiquitous 'sentinels' are the body's first-line defense against infection, charged with detecting invading microbes and initiating defensive responses through the production of a variety of vasoactive and proinflammatory mediators. A variety of pattern recognition systems, including the Toll-like receptors, are basic to this process. Macrophages also play a critical role in antigen presentation to activate adaptive immune responses.

In the case of RNA viral infections, the presence of single-stranded and double-stranded viral RNA in the cytoplasm is probably the principal stimulus leading to macrophage activation, resulting in an increased capacity for microbial killing and the synthesis and release of a variety of proteins and small molecules that alert the body to the presence of an invader and lay the groundwork for nonspecific and virus-specific countermeasures. The former include the release of proinflammatory mediators such as interleukin-1- β , interleukin-6, tumor necrosis factor- α , and nitric oxide, a potent stimulant of vasodilatation. Activated macrophages also synthesize and display tissue factor on their surfaces, triggering the extrinsic coagulation pathway. In addition to this set of nonspecific responses, macrophages help to initiate an antigen-specific immune response by processing the microbes they have ingested and presenting peptide fragments in association with major histocompatibility complex molecules for recognition by CD4 + lymphocytes.

When triggered by a localized process, such as the entry of bacteria through a break in the skin, mediators released by macrophages produce a variety of effects: dilatation of blood vessels, increased permeability of their endothelial linings, initiation of coagulation leading to fibrin deposition, and activation of endothelial cells in a manner that favors the adhesion of platelets and an influx of neutrophils, monocytes, and other inflammatory cells into the affected region. These physiologic changes are responsible for the swelling, heat, redness, pain, and pus formation that characterize an infected wound or other localized inflammatory process. Fever and other systemic signs and symptoms may also occur, depending on the extent to which inflammatory mediators produced at the site of infection enter the plasma.

When restricted to a small portion of the body, the changes in vascular function induced by activated macrophages and other inflammatory cells are beneficial, since they permit antibodies, complement, neutrophils, and other effector cells to leave the bloodstream and enter the affected area. In viral hemorrhagic fever, by contrast, the release of the same mediators by monocytes and macrophages in lymphoid organs and tissues throughout the body has a catastrophic effect, causing diffuse dilatation and increased permeability of blood vessels that result in hypotension and shock. The fundamental role of host responses in causing these basic signs and symptoms of illness has been demonstrated to varying degrees for many forms of viral hemorrhagic fever, including Crimean-Congo hemorrhagic fever, hantaviral infections, yellow fever, and dengue.

When the hemorrhagic fever syndrome was first described in the 1950s, increased vascular permeability and hemorrhage were assumed to result from direct viral infection of endothelial lining cells of blood vessels or their injury by virus-encoded products. Early designations for the disease therefore included such expressions as 'capillary toxicosis'. In the current scenario, by contrast, the hypotension and coagulopathy of viral hemorrhagic fever are seen as normal physiologic responses of endothelial cells to circulating inflammatory mediators – a system-wide version of the same changes that occur in a localized inflammatory response. The fact that vascular dysfunction is a response to host mediators does not mean, of course, that viral invasion of the vascular lining cannot also occur. Infection of endothelial cells has in fact been identified, but as a late consequence, rather than a causative mechanism of illness. Thus, in cynomolgus macaques infected with Ebola Zaire virus, careful examination of blood vessels in groups of animals killed on each day postinfection has found virus-infected cells only toward the end of the disease course. Infection of the endothelium has also been seen in tissues collected at autopsy of humans dead from other diseases, including Crimean-Congo hemorrhagic fever. These findings suggest that changes in endothelial cell function induced by inflammatory mediators over the course of illness render them susceptible to viral infection.

Suppression of Type I Interferon Responses

Once a virus has entered a cell, the type I interferon system is the primary barrier to its further dissemination. Triggered by Toll-like receptors and other pattern recognition molecules, a complex web of intracellular signaling leads to the expression of an array of proteins that collectively produce an 'antiviral state', inhibiting viral replication. At the same time, the infected cell secretes

interferons, inducing a similar resistance to viral infection in neighboring uninfected cells. The ability of the hemorrhagic fever viruses to spread rapidly from their initial site of entry therefore implies that these agents are able to evade or suppress the type I interferon system, and research has shown that this is in fact the case. Ebola virus, for example, encodes two different interferon antagonists: one protein that suppresses the initial production of interferon by the infected cell and another that prevents the cell from responding to exogenous type I or type II interferon. A number of agents from the other three viral families, including Rift Valley fever virus, dengue virus, and certain arenaviruses, have also been shown to block interferon responses, through a variety of mechanisms.

The importance of the interferon system to the control of viral dissemination helps to explain why all of the hemorrhagic fever agents are RNA viruses. Such agents generate double-stranded RNA molecules, a strong stimulus for interferon production, during the course of gene transcription and genome duplication. To be able to persist in their natural reservoir species, it is therefore essential that these viruses block interferon responses to at least the degree necessary to ensure their replication, dissemination, and transmission to a new host. When humans encounter a new RNA virus, the outcome of infection will depend in part on whether the viral interferon antagonist proteins are able to interact with and inhibit the interferon machinery of a human cell. Given the myriad of viruses that exist in nature and the relative rarity of severe viral zoonoses, it appears that the majority of cross-species transfers do not result in suppression of the human interferon system. In the case of the hemorrhagic fever viruses, however, it appears that virus-encoded interferon antagonist proteins suppress the human interferon system so effectively that the agents are able to disseminate rapidly, causing systemic infection of monocytes and macrophages and a massive inflammatory response.

Direct Tissue Damage

All of the hemorrhagic fever viruses infect human monocytes and macrophages, but they differ considerably in their ability to infect other types of cells. At one end of the spectrum, dengue virus principally infects only those two cell types, plus dendritic cells, without causing their death. At the other extreme, Ebola and Marburg viruses are apparently capable of infecting virtually every type of cell in the body except for lymphocytes and neurons. This lack of host cell specificity appears to reflect the ability of the filoviral surface glycoprotein to bind to widely distributed cell-surface lectins. Material released from dying cells is itself a stimulus for inflammation, contributing further to the fulminant systemic illness.

Most types of viral hemorrhagic fever produce a degree of tissue damage intermediate between dengue and filoviral hemorrhagic fever, with the liver as the principal target. Hepatic involvement probably begins with the spread of virus through the bloodstream to fixed macrophages (Kupffer cells) in sinusoids, from which infection then extends to parenchymal cells, giving rise to increased levels of 'liver-associated' enzymes in the plasma. Hepatic injury is a prominent feature of yellow fever, causing the jaundice that gave the disease its name, and is seen in some cases of Rift Valley fever. It also occurs in Crimean-Congo hemorrhagic fever and some other infections, but without producing the high levels of bilirubin that lead to jaundice.

Failure of Adaptive Immune Responses

Because the initial signs and symptoms of viral hemorrhagic fever are not caused by the replicating virus, but by host inflammatory mediators, they all begin in a similar manner. As infection progresses, however, specific virus–host interactions come into play that determine the precise nature of the illness. Of critical importance to the final outcome is the host's ability to generate the antigen-specific immune responses that are needed to contain and eliminate a viral infection. Two factors appear to determine whether such responses can take place quickly enough and strongly enough to ensure survival: (1) the ability of dendritic cells or macrophages to present viral antigens to lymphocytes and (2) the extent to which the lymphocytes themselves are destroyed through programmed cell death.

Dendritic cells are the major antigen-presenting cells of the body, and they are also a site of replication for hemorrhagic fever viruses. In a number of cases, such as Lassa fever and Ebola virus infection, it has been shown that infected immature dendritic cells are unable to mature, migrate to lymph nodes, present antigens, and stimulate naïve lymphocytes to proliferate. By contrast, such impairment does not appear to take place in milder forms of hemorrhagic fever, such as dengue, helping to explain its lower lethality.

The second phenomenon, the massive death of lymphocytes through apoptosis, is now recognized to be a component of septic shock resulting from Gram-negative bacterial infections, and studies suggest that it is a feature of all severe infections. Even though they remain uninfected by virus, natural killer cells and T cells appear to be especially vulnerable to programmed cell death during the course of illness, a process that is apparently driven by the action of such proapoptotic mediators as tumor necrosis factor- α and Fas ligand, and perhaps by changes in cellular metabolism that accompany severe disease. The fact that impairment of dendritic cell function and a massive loss of lymphocytes both occur during the course of Ebola hemorrhagic fever helps to explain why so few patients recover from the disease.

Antiviral Therapy

Of the many antiviral drugs now in clinical use, only the nucleoside analogue ribavirin has proven to be active against some (but not all) of the hemorrhagic fever viruses. Although it inhibits the replication of a wide range of viruses *in vitro*, ribavirin is licensed for the treatment of respiratory syncytial virus infection in infants, although it is only used in extremely critical cases, and for hepatitis C, in

combination with interferon. Limited clinical experience has indicated that the drug is also beneficial for the treatment of Lassa fever and for the Old World hantaviral infection, hemorrhagic fever with renal syndrome. As is generally true of antiviral therapy, treatment is most effective when begun early in infection. The drug produces a reversible hemolytic anemia, and evidence of teratogenicity prevents its use in pregnant women. Studies in nonhuman primates suggest that ribavirin would also be of value for the therapy of New World arenavirus infections. Surprisingly, it has no effect on filoviral replication. Although active against yellow fever in a rodent model, the drug had no impact on infection in macaques.

Ribavirin acts as a guanosine analogue. Its mechanisms of action include decreasing the size of intracellular guanosine di- and triphosphate pools, inhibiting 5' cap formation on viral messenger RNA, and interfering with RNA-dependent RNA polymerase activity. Possibly because of these multiple mechanisms of action, no development of viral drug resistance has ever been observed. Ribavirin's ability to block the replication of some RNA viruses, but not others, remains unexplained.

Favipiravir (T-705) is a recently developed compound now under development for the treatment of influenza, that has also shown efficacy against hemorrhagic fever virus infections in a number of animal model studies. Favipiravir inhibits the viral RNA-dependent RNA polymerase by acting as a purine nucleotide analog. While favipiravir is not licensed for use in humans, it has been shown effective in animal models against Ebolavirus, Rift Valley fever virus, South American arenaviruses Junin and Machupo viruses, hantaviruses and yellow fever virus in addition to being tested in clinical trials for the treatment of influenza virus infection.

Human convalescent plasma has been widely used for the postexposure prophylaxis or treatment of viral hemorrhagic fever in countries where these diseases are endemic, but no controlled trials have been conducted to assess its actual efficacy. The best evidence of a beneficial effect has been obtained for Argentine hemorrhagic fever, for which immune plasma is currently the standard treatment. High-titer convalescent plasma was effective in treating laboratory primates for Lassa fever, but the results of limited trials in humans were not encouraging.

Causative Agents of Viral Hemorrhagic Fever

Arenaviruses

The arenaviruses (from the Latin word *arena* meaning 'sand') are spherical, lipid-enveloped viruses that frequently entrap host ribosomes during their formation, giving them a 'sandy' appearance on electron microscopy. The genome consists of two separate RNA molecules, which are ambisense, such that proteins are encoded in both directions on the same strand. The large (L) strand encodes the RNA-dependent RNA polymerase and a Z protein, which is thought to play a structural role, linking the nucleocapsid to the lipid membrane. The small (S) strand encodes a nucleoprotein, which binds to the genomic RNA, and the two surface glycoproteins, G1 and G2.

The arenaviruses that cause hemorrhagic fever are divided into two groups: (1) 'Old World' agents, including Lassa fever virus, which is found in west Africa and Lujo virus which recently emerged in southern Africa and (2) a number of 'New World' viruses that cause severe disease in areas of South America and in the southwestern United States. Each virus is named according to the location where it was first isolated. All of them are maintained in rodents, among which they spread through direct contact or excretions; none is transmitted by an arthropod vector. Human infection occurs through the handling, butchering, or ingestion of infected animals or through exposure to their aerosolized urine or feces. The epidemiology of each disease is therefore determined by the frequency and pattern of human-rodent contact.

Lassa fever virus

Although the actual numbers are not known, serosurveys suggest that as many as 100 000 people develop Lassa fever each year in west Africa, principally in the three coastal countries of Liberia, Guinea, and Sierra Leone. The causative agent is maintained through continuous transmission in the multimammate mouse (*Mastomys natalensis*). The high incidence of human infection reflects frequent contact with these animals, which infest living areas and are sometimes used as a source of food.

The majority of cases of Lassa fever are asymptomatic or mild, but among those patients sick enough to require hospitalization, the case-fatality rate is 15–20% or higher. Outbreaks have occurred in west African hospitals where the lack of proper infection control measures have allowed contact with body fluids of patients or the reuse of contaminated syringes. The occasional entry of infected travelers into Europe or the United States has not led to secondary transmission.

In contrast to other types of viral hemorrhagic fever, Lassa fever usually develops gradually, after a 1–3-week incubation period. The syndrome includes fever, sore throat, headache, and myalgias, which may progress to severe illness characterized by neurologic dysfunction and shock. Occasional cases show signs of meningitis, and virus has been isolated from the cerebrospinal fluid of a limited number of patients. Unlike the New World viruses described later, however, Lassa fever virus does not produce a delayed neurologic syndrome. Although hemorrhage may occur in severe cases, it is not a prominent part of the syndrome. Deafness is a major complication of the disease.

Virus may be isolated from the blood throughout the course of Lassa fever, and it is also present in urine, pharyngeal secretions, and other body fluids. The prognosis at the time of hospital admission is strongly determined by the level of virus in the blood; patients with high levels are at greatest risk of death. The severity of hepatic involvement, as indicated by the serum aspartate aminotransferase level, also correlates with a fatal outcome. A majority of patients already have IgM antibody to Lassa virus at the time of hospital admission, and about half have IgG. Antibody and virus may cocirculate throughout the course of the illness, with no evident relationship to the eventual outcome. The induction of cell-mediated immunity appears to be a more important factor than the humoral response in controlling and eliminating viral replication.

A large study in Sierra Leone that compared Lassa fever patients treated with ribavirin with previous patients with a similar severity of illness demonstrated a significant benefit of oral or intravenous therapy. For those with high viremia or significant liver involvement, treatment with oral or intravenous ribavirin reduced mortality from roughly 50% to <20%. Therapy was most effective if begun within 6 days after the onset of illness. Immune plasma was effective in treating Lassa virus–infected laboratory primates, either alone or in combination with ribavirin, but did not provide any benefit in limited clinical trials, perhaps because titers of neutralizing antibodies were too low to produce an effect. A number of experimental vaccines are effective in laboratory animals, but none has advanced to human studies. At present, control measures focus on reducing exposure to the virus by eliminating rodents from inhabited areas.

Lujo virus

Lujo virus was identified in an outbreak of hemorrhagic fever cases that originated in Lusaka, Zambia but carried over to Sandton, South Africa where the index case was transferred for treatment. There were a total of five cases with four fatalities. In contrast to Lassa fever, which is rarely transmitted person to person, three patients acquired their infection through exposure to the index patient or a secondary case, and one through contact with contaminated materials. The one survivor was treated with ribavirin following disease onset. Lujo virus was determined to be genetically similar to Old World arenaviruses, but within a distinct genetic branch that was more similar to New World viruses.

Argentine hemorrhagic fever (Junin) virus

Argentine hemorrhagic fever, caused by Junin virus, is the most common human arenaviral infection in the Western Hemisphere. Until vaccination was introduced for populations at greatest risk, up to 600 cases were diagnosed each year in grassland areas of Argentina. The maintenance host is a field vole (*Calomys* species) that lives along the margins of cultivated fields. Unlike in Lassa fever, exposure to Junin virus occurs during farming activity, most commonly during the harvest season. Infection does not spread from person to person.

The majority of Argentine hemorrhagic fever patients suffer a severe illness; about one-third develop life-threatening hemorrhagic or neurologic complications. The overall case-fatality rate is ~15%. Compared to other types of viral hemorrhagic fever, there is little hepatic involvement. Patients tend to develop a relatively low viremia, and the resolution of illness is accompanied by the development of neutralizing antibodies. In a small percentage of patients, neurologic signs and symptoms develop 4–6 weeks after resolution of the acute illness. This encephalitic phase tends to resolve uneventfully, but is occasionally fatal.

Treatment with pooled plasma collected from survivors reduced mortality from Argentine hemorrhagic fever in a large clinical trial, provided it was initiated before the eighth day of illness. Therapy has since been standardized, based on the titer of neutralizing antibodies in the plasma and the weight of the recipient. Although antiserum treatment reduces the severity of the acute illness, it does not prevent development of the delayed neurologic syndrome.

A live, attenuated variant of Junin virus (Candid 1) has been in use as a single-dose vaccine in Argentina for more than a decade. Its efficacy was demonstrated in a placebo-controlled trial involving 6500 agricultural workers, in which only one new case occurred among vaccine recipients, compared to 22 among controls. It has since been administered to several hundred thousand adults at risk of infection, and it is now being used in children. Evidence from laboratory animals indicates that the vaccine also cross-protects against Machupo virus.

Other new world arenaviruses

Three other arenaviruses cause severe illness in South America, but are responsible for far fewer cases per year. Bolivian hemorrhagic fever, which occurs in savannah regions of that country, is caused by Machupo virus. The agent is maintained in a field vole (*Calomys callosus*). As in the case of Lassa virus infection, human exposure occurs through household exposure to excretions of infected animals. Its incidence has been reduced by rodent trapping efforts. The overall case-fatality rate is about 15%. Severe hemorrhage is more common in Bolivian than in Argentine hemorrhagic fever, while the latter shows a greater incidence of neurologic damage.

Another severe arenaviral disease was recognized in 1990, when a patient in Sabia, Brazil, died from an illness initially believed to be yellow fever. A virologist investigating the case became infected in the laboratory, but survived after a prolonged febrile illness. A second accidental infection occurred in 1994, when an investigator in the United States became infected through a centrifuge accident. Treatment with intravenous ribavirin was started 2 days after the onset of fever, and he recovered uneventfully. The third agent, Guanarito virus, was identified in 1989, when an outbreak of severe hemorrhagic fever occurred in central Venezuela. The virus is maintained in cotton rats and cane mice, and male agricultural workers are at greatest risk of infection. Variation in annual disease incidence appears to reflect changes in the rodent population. More than 200 cases of Venezuelan hemorrhagic fever have so far been reported, with a case-fatality rate of about 33%. Arenaviruses have also been isolated in two areas of the United States. The Whitewater Arroyo virus, first recognized in the mid-1990s, has been responsible for scattered cases of illness in California, but the Tamiami virus, identified in rodents in Florida, has not been linked to human disease.

Bunyaviruses

The bunyaviral genome consists of three separate RNA molecules, which for most members of the viral family are all of negative polarity. The large (L) segment encodes the RNA-dependent RNA polymerase, the middle (M) the two virion surface glycoproteins, and the small (S) a nucleoprotein that binds to the viral genome to form the nucleocapsid. The S segment also encodes a small

nonstructural (NSs) protein that, at least in the case of Rift Valley fever virus, has been shown to act as an inhibitor of type I interferon production by blocking the general host transcription of new messenger RNA in the nucleus, in part by promoting degradation of the dsRNA-dependent protein kinase (PKR).

The bunyaviruses that cause hemorrhagic fever have the widest geographic distribution of the agents discussed in this article. Most are transmitted to humans by the bites of arthropods, with the important exception of the hantaviruses, which are spread through the aerosolized excretions of infected rodents. With the exception of Rift Valley fever, which can occur as large mosquito-borne epidemics, most cases of bunyaviral hemorrhagic fever are sporadic and solitary. Recent years, have seen a marked increase in cases of Crimean-Congo hemorrhagic fever in Turkey and Iran, where almost all infections appear to result from exposure to infected ticks. In addition to the fever, vascular leak and rapid development of shock that characterize all types of viral hemorrhagic fever, some bunyaviral infections have unique features: renal disease, in the case of Old World hantaviral infections; ophthalmic and neurologic involvement in Rift Valley fever; and fulminant respiratory failure in the case of New World hantaviral disease.

Crimean-Congo hemorrhagic fever virus

As its name implies, Crimean-Congo hemorrhagic fever occurs over a vast geographic area. The virus was first isolated during an outbreak in the Crimean peninsula of the Soviet Union during World War II. During the 1950s, another novel agent was recovered from a patient in Congo, and testing subsequently showed that the two pathogens were identical. Crimean-Congo hemorrhagic fever has since been found in a huge arc extending from western China across southern Asia into eastern Europe, and from Turkey southward to the tip of Africa. In all of these areas, the virus is maintained through continuous infection of ticks, which carry it to a variety of animals, including rodents, hares, cattle, goats, sheep, and birds, all of which may serve as amplifying hosts. With the possible exception of ostriches, none of these animals show signs of illness. The wide geographic distribution of Crimean-Congo hemorrhagic fever virus appears to be explained by the role of migratory birds in carrying infected ticks.

Humans are exposed to the virus in several ways. Most cases occur singly, when inhabitants of rural areas are bitten by infected ticks. Small outbreaks can also take place when slaughterhouse employees handle meat from infected animals or are exposed to aerosolized body fluids. Interestingly, there is no report of human infection through meat purchased in a market, suggesting that the virus is inactivated soon after the death of its animal host. Human-to-human transmission through contact with body fluids takes place most often in hospital settings, before the nature of a patient's illness has been recognized. Spread to health care workers can be prevented through standard barrier nursing measures.

The clinical course of Crimean-Congo hemorrhagic fever resembles that of other types of severe hemorrhagic fever. After a 3–6-day incubation period, it typically begins with the sudden onset of high fever, severe myalgias, abdominal pain, and vomiting. Gastrointestinal symptoms are sometimes so prominent that patients undergo unneeded surgery, exposing the hospital staff to infection. The presence of hyperemia of the face and chest, conjunctival congestion, and a petechial rash on the trunk may help to distinguish the disease from other febrile syndromes. Extensive bruises on the extremities and oropharyngeal and gastrointestinal bleeding often appear during the first week. As the illness progresses, a fall in blood pressure leads to shock, multiorgan failure, and coma. The case-fatality rate has variably been reported to range from 5% to 50%.

Laboratory tests during the course of Crimean-Congo hemorrhagic fever show shifts in white blood cell counts, as described earlier, with rising levels of liver enzymes in the plasma and the development of disseminated intravascular coagulation. Patients with the most severe liver involvement and coagulopathy are most likely to die from the disease. A specific diagnosis can be made through antigen-capture enzyme-linked immunosorbent assay or polymerase chain reaction testing of serum samples. Virus-specific IgM and IgG can generally be detected within 10 days after the onset of illness.

Ribavirin therapy appears to be beneficial, based on reports of its use in hospital-based outbreaks, but no controlled trials have been performed. Research on the disease has been hindered by the fact that the virus does not cause illness in nonhuman primates or other laboratory animals, except for suckling mice. Limited autopsy data have shown that the disease shares many features with Ebola hemorrhagic fever, including extensive infection of macrophages, infection and necrosis of hepatocytes, and a massive loss of lymphocytes.

Rift Valley fever virus

Rift Valley fever virus causes disease in livestock and humans across the entire extent of sub-Saharan Africa, extending north along the Nile Valley into Egypt. Both isolated cases and large mosquito-borne outbreaks occur. An epidemic in 1977 involved more than 200 000 human infections in Egypt, with a case-fatality rate of 0.3%. The recent spread of infection across the Red Sea to Yemen, carried by the sheep trade, has raised concern that the virus may become established in the Middle East. The virus is maintained through cyclic infection of *Culex* mosquitoes and rodents. Large epidemics are associated with increases in vector populations, when *Aedes* mosquitoes and biting flies carry the virus to farm animals, particularly sheep, and to humans, both of which develop high viremia and thus serve as amplifying hosts for further transmission. Current methods of satellite imaging and rainfall prediction are facilitating advanced planning for disease outbreaks. The virus induces abortion in livestock, and placental tissues are a source of infection for farmers. People who butcher animals may also acquire the disease through contact with contaminated blood or tissues.

Rift Valley fever is highly varied in its clinical manifestations. The majority of patients develop a nonspecific illness with fever, headache, myalgias, and gastrointestinal symptoms, which usually resolves within 1–2 weeks. About 5% develop hemorrhagic fever, in which a petechial rash and mucosal bleeding, accompanied by signs of liver involvement, develop within the first few days of illness. Severely ill patients show elevated circulating liver enzymes and jaundice, and may die from hepatic failure. Others develop central nervous system disease, in which neurologic abnormalities appear during the second week of illness beginning with

headache and progressing to severe or fatal encephalitis. A disabling complication unique to Rift Valley fever is ocular involvement, manifested as retinal inflammation and hemorrhage, often bilateral, which can result in partial or complete loss of vision in up to half of cases. These changes may develop days to weeks after the acute illness has resolved.

There is no specific therapy for Rift Valley fever. Ribavirin has been protective in animal models of the disease, but has given equivocal results in humans. A formalin-inactivated, cell culture–derived vaccine is in widespread use in Africa, and is available in the United States as an investigational new drug. Control measures during outbreaks focus on vector control and vaccination of livestock to restrict the spread of infection.

Old world hantaviruses

The expression ‘hemorrhagic fever with renal syndrome’ designates a spectrum of diseases caused by various species of hantaviruses that are found across Eurasia, from the Korean peninsula and China to Scandinavia and the Balkans. The agents are maintained through chronic infection of various rodent species. The most severe form of illness occurs in the eastern portion of the former Soviet Union, Korea, and China, where it has been recognized for centuries. When it came under intensive investigation as a result of the unexpected occurrence of severe illness among UN soldiers during the Korean War, the disease became known as Korean hemorrhagic fever. It is estimated that more than 100 000 cases occur annually in rural areas of China. Its causative agent, Hantaan virus, is carried by the field mouse *Apodemus agrarius*. Seoul virus, which chronically infects urban rats, causes a less severe form of disease. In Scandinavia, the Puumala species of hantavirus also causes a milder illness, designated nephropathia endemica. Dobrava virus, a hantavirus indigenous to the Balkans, produces a more severe disease that resembles Korean hemorrhagic fever.

The epidemiology of hemorrhagic fever with renal syndrome is determined by the frequency with which humans come into contact with virus-infected animals. Farmers, soldiers, and others whose daily activities bring them into close proximity with rodents or with materials contaminated by their excretions are at greatest risk of infection. Contact may also occur within homes, especially when the coming of winter causes rodents to move indoors in search of warmth. Laboratory colonies of mice and rats were at one time a source of infection, but screening programs have now eliminated infected animals.

Hemorrhagic fever with renal syndrome develops through five stages: febrile, hypotensive, oliguric, diuretic, and convalescent. Following an incubation period of 1–4 weeks, it begins with the abrupt onset of high fever, chills, malaise, headache, and muscle pain. Flushing of the skin and conjunctival hemorrhages may be noted on physical examination. Laboratory tests show an increase in the total white blood cell count, with mild to moderate thrombocytopenia. After about a week, a hypotensive stage begins, which may last from hours to days; it is during this phase that most patients seek medical attention. A specific diagnosis can usually be made, based on the presence of virus-specific IgM in the serum. Hemorrhagic phenomena, including mucosal bleeding, may occur, and some 10–15% of patients go into shock.

The stage of hypotension is also characterized by the first signs of renal dysfunction, including proteinuria and a loss of urine concentrating ability. With the onset of the subsequent oliguric phase, the blood pressure may become elevated, urea nitrogen and creatinine levels increase, and the urine output falls. The combination of hypertension and impaired coagulation may lead to intracerebral hemorrhage. The introduction of hemodialysis has reduced the case-fatality rate. Recovery is heralded by the onset of the diuretic phase, usually toward the end of the second week of illness. The final convalescent phase lasts days to weeks; anemia and loss of urine concentrating ability may persist beyond that time. Ribavirin therapy can improve the outcome of illness, provided it is initiated early in the disease course.

In contrast to the severe illness just described, nephropathia endemica (discussed earlier) has a shorter, biphasic course and a lower case-fatality rate. It generally begins with the sudden onset of fever, chills, headache, and myalgias. As the fever resolves, renal dysfunction appears, with proteinuria, loss of urine concentrating ability, and elevated blood urea nitrogen and creatinine. A brief period of oliguria is followed within days by polyuria and the resolution of illness. Hemorrhage is not observed.

New world hantaviruses

Up until 1993, hantaviruses were known only as the causative agents of hemorrhagic fever with renal syndrome in Europe and Asia. In that year, however, an outbreak of an acute febrile illness with rapidly progressive respiratory failure and a high case-fatality rate was reported in the Four Corners area of the American Southwest. To the great surprise of investigators, a previously unknown species of hantavirus, now designated Sin Nombre virus was isolated from patients. The agent is now known to chronically infect local deer mice, and retrospective studies found that the disease has occurred sporadically in the region for decades. The surge of cases that brought the disease to medical attention in 1993 was an indirect effect of increased rainfall the previous year, associated with an El Niño phenomenon, which produced an abundant food supply for local deer mice, a massive expansion in their population, and greater human exposure.

Because the principal disease manifestation of patients in the Four Corners area was rapidly progressive respiratory failure, the newly recognized condition was designated hantavirus pulmonary syndrome. Over the subsequent two decades, many additional cases have been diagnosed in numerous sites in North, Central, and South America. Within each geographic area, the local hantavirus is maintained in a unique rodent host. Many of these viruses are now recognized as discrete species, named according to the location where they were first isolated. Most produce a similar illness, with the exception of the Andes virus, found in Chile and Argentina, which is the only agent for which person-to-person transmission has been clearly demonstrated.

As in the case of the Old World hantaviral diseases, humans become infected with the agents of hantaviral pulmonary syndrome through exposure to the excretions of infected rodents, probably in the form of aerosols of dried urine or feces. Following an incubation period of 1–3 weeks, there is an abrupt onset of fever, chills, myalgias, headache, and nonspecific gastrointestinal

symptoms. After 3–4 days, the patient develops respiratory distress, which rapidly worsens. The chest X-ray is normal during the early, febrile phase of illness, but bilateral pulmonary edema, typical of acute respiratory distress syndrome, develops rapidly once respiratory symptoms appear. The majority of patients who are hospitalized at this point require intubation and mechanical ventilation. Blood tests show an increased white blood cell count, with immature granulocytes and immunoblasts, and a drop in the platelet count. About half of patients develop irreversible lactic acidosis and shock and die within 2–4 days, while the rest undergo a slow, but complete recovery. Although ribavirin is active against these viruses in cell culture, clinical studies have failed to demonstrate any benefit from treatment, probably because patients are already too sick at the time of hospital admission for an antiviral drug to modify the further course of illness. The use of Extracorporeal Membrane Oxygenation (ECMO) has been shown to be effective at reducing predicted mortality in patients demonstrating advanced shock or respiratory failure due to onset of pulmonary edema.

The underlying physiologic abnormality in hantaviral pulmonary syndrome appears to be a vascular leak that is largely limited to pulmonary blood vessels, caused by the effects of inflammatory mediators on endothelial lining cells. Autopsy studies have revealed viral antigens in endothelial cells of the lungs, where interstitial mononuclear cell infiltrates and hyaline membranes are also present. Research on the disease has benefited from the recent development of a model in hamsters infected with the Andes hantavirus.

Filoviruses

The genus name of the filoviruses (from the Latin *filum* meaning thread) reflects their unique filamentous structure. The two species, Marburg and Ebola, are identical in morphology. Virions average 80 nm in diameter, but may be up to 1 μ m in length. The genome consists of a single 19-kb strand of negative-sense RNA. Transcription of viral genes and replication of the genome are performed by a complex of the RNA-dependent RNA polymerase and three other virus-encoded proteins. Marburg and Ebola viruses replicate in an identical manner, except that the primary glycoprotein gene product of all Ebola species is a C-terminally truncated protein ('sGP') that is secreted into the extracellular medium. Production of the full-length membrane GP requires the post-transcriptional addition of a nucleotide to its messenger RNA. No role has been identified for sGP in the pathogenesis of Ebola hemorrhagic fever in humans, but it might contribute to viral persistence in the maintenance host.

Ebola and Marburg viruses infect a far broader range of host cells than any other agent of viral hemorrhagic fever. The virus initially disseminates to monocytes and macrophages in lymph nodes, liver, spleen, and other tissues, from which it spreads further to infect parenchymal cells. Only lymphocytes and neurons are known to remain free of infection. Replication results in the formation of large nucleocapsid inclusion bodies and the budding of hundreds to thousands of new virions from the cell surface. Infected cells undergo death through necrosis.

The filoviruses are without doubt the most virulent of the causative agents of viral hemorrhagic fever, and they are certainly the most mysterious. The animal reservoir in which they are maintained in nature has not yet been demonstrated conclusively. Marburg virus has been isolated from bats in central Africa, and evidence suggests that these animals also harbor Ebola viruses, though it is not certain that they are the actual animal reservoir. The route by which humans and great apes become infected has also not been conclusively identified. Until 1989, all evidence indicated that the homeland of the filoviruses was central Africa, but in that year a novel variant of Ebola virus was unexpectedly discovered in nonhuman primates held in a quarantine facility in Reston, Virginia, after importation from the Philippines (see 'Ebola virus').

Marburg virus

Marburg was the first filovirus to be discovered, when the inadvertent importation of infected monkeys from Uganda into Europe in 1967 caused outbreaks of hemorrhagic fever among vaccine plant workers in Marburg, Germany, Belgrade, and Yugoslavia. Exposure to infected monkeys or their tissues resulted in severe disease in 31 people, of whom 7 died. Eight doctors and nurses caring for the patients also acquired the infection, but no further transmission occurred.

Since that first outbreak, all cases of Marburg hemorrhagic fever have occurred in Africa. For more than three decades, these consisted of a total of only six sporadic infections, for which no source could be determined. In 2000, however, a large epidemic came to light in Watsa, in northeastern Democratic Republic of the Congo (DRC). More than 150 cases were eventually confirmed, with a fatality rate of >80%. Genetic analysis of viral isolates showed that the epidemic had resulted from multiple independent introductions of virus into the local community of gold miners, with little secondary spread of infection. Because the miners were exposed to vast numbers of bats and their excreta during their time underground, this outbreak provided support for the proposal that bats were the reservoir host. However, no infected animals were identified.

In 2005, Marburg virus appeared unexpectedly in Angola, far from any previous site of human infection, causing some 250 cases of illness with a case fatality rate that approached 90%. Unlike in the Watsa epidemic, only a single strain of virus was isolated. The source of infection was again not known. The first known cases occurred in the pediatric ward of a provincial hospital, where transmission was amplified through the reuse of contaminated blood transfusion equipment.

Ebola virus

Ebola virus first came to the attention of the world scientific community in 1976, when two large epidemics of hemorrhagic fever occurred almost simultaneously in Zaire (the present DRC) and Sudan. The causative agents of the two outbreaks were found to be distinct, and are now recognized as separate viral species. The Zaire epidemic was centered at a mission hospital, where treatment

routinely included injections of drugs or vitamins, using syringes that were rinsed in water between patients. The inoculation of an unidentified index case of Ebola hemorrhagic fever apparently was followed by the inadvertent transmission of virus by contaminated syringes to nearly 100 other patients, all of whom developed fatal disease. Many of the doctors, nurses, and family members who cared for these patients also became infected; the final death toll was 280 of 318 cases. Another large outbreak caused by the Zaire ebolavirus occurred in Kikwit, DRC, in 1995, with a case-fatality rate exceeding 80% among more than 300 patients. Amplification in a hospital once again contributed to the large size of the epidemic: One of the initial patients developed severe abdominal pain and underwent surgery, spreading the infection to the entire operating team, apparently through exposure to aerosolized blood. Beginning in the spring of 2014, a significant outbreak of Ebola hemorrhagic fever with over 10,000 cases in Guinea, Liberia and Sierra Leone extended the endemic area of Zaire ebolavirus far to the northwest of its previously known range.

The origin of the 1976 outbreak caused by Sudan ebolavirus, which involved almost 300 patients, was also unidentified. The within-hospital transmission of virus from the initial patients to the family members and health care workers who cared for them without gloves or other forms of protection again played a major role in the large size of the outbreak. In contrast to epidemics caused by Zaire ebolavirus, the case-fatality rate for that epidemic and for two more in 1979 and in 2000 were all 50%. The 2000 outbreak, which occurred in Gulu, Uganda, was the largest yet recorded, with 425 patients.

Beginning in 1996, a new epidemiologic pattern was observed in central Africa, in which humans became infected with Zaire ebolavirus through contact with sick or dead chimps or gorillas. In the first known outbreak of this type, 19 Gabonese villagers who butchered and ate a chimp found dead in the forest developed fulminant hemorrhagic fever, and most of them died. The virus has spread among populations of great apes in Gabon and neighboring Republic of Congo, causing both a massive die-off of these animals and repeated epidemics among local residents. Because nonhuman primates die quickly from infection, they cannot serve as a natural reservoir for Ebola virus. It has been proposed that bats are the original source of infection, but conclusive proof that bats are the sole reservoir is still lacking. However, serological studies have suggested evidence of Ebola virus, or a closely related virus, in bats in China and Bangladesh suggesting that filoviruses are more widespread than has been thought. A third Ebola viral species, Tai Forest ebolavirus (formerly known as Ivory Coast), caused the death of a chimp in that country in the 1990s, and almost killed the scientist who performed its necropsy. The virus has not been detected since.

In fall 2007 an outbreak of hemorrhagic fever virus occurred in Western Uganda with 192 suspected and 42 laboratory confirmed cases of Ebola virus infection. This outbreak had a lower case fatality rate (~34%) than previous outbreaks of Ebola hemorrhagic fever. The causative agent for this outbreak was subsequently determined to be a novel virus species which was subsequently named Bundibugyo ebolavirus.

The fifth species of Ebola virus, the enigmatic Reston agent, made its world debut in 1989, not in the rain forests of Africa, but in a monkey quarantine facility in suburban Virginia, where it caused an outbreak of lethal illness in macaques recently imported from the Philippines. Several similar episodes occurred at primate holding facilities over the next few years, until the source company in the Philippines was shut down. Reston ebolavirus re-emerged in 2008 in pig populations in the Philippines. Subsequently, pigs have been shown to be a significant potential reservoir for Reston ebolavirus with bats playing a critical role in the dissemination of the virus within and between pig populations. Fortunately, there is no evidence that Reston ebolavirus infects humans as there have been no reports of human cases among people working with infected animals. These data suggest that Reston ebolavirus is avirulent for humans. However, it seems prudent to conclude that its pathogenic potential for humans is not known.

Flaviviruses

The flaviviruses have a positive-sense genome that is capped but is not polyadenylated, thus resembling a strand of messenger RNA. Following fusion of a virion with the cell membrane, the genome is released into the cytoplasm, where it is translated into a single polyprotein that is cleaved by host cell enzymes, and by a protease encoded toward the end of the viral genome, to form individual proteins. A complex of several viral nonstructural proteins then uses the viral genome as a template to synthesize negative-sense 'antigenomes', which in turn serve as templates for new genome formation.

Of the numerous flaviviruses that infect humans, five can produce a hemorrhagic fever syndrome. Two of them, Omsk and Kyasanur Forest viruses, resemble many of the viruses discussed earlier, in that they are maintained in rodents. The reservoir for Alkhurma virus, which is closely related to Kyasanur Forest disease virus, has not yet been determined. Yellow fever virus is maintained through infection of forest primates in Africa and South America, but is capable of maintaining itself through mosquito transmission from person to person. In contrast, dengue has evolved from an infection of wild primates in Southeast Asia into a disease that can persist solely in human populations. As will be discussed later, the degree of human adaptation appears to correlate inversely with the severity of the disease: Yellow fever virus can cause full-blown hemorrhagic fever, while primary dengue infections are relatively mild. The occurrence of dengue hemorrhagic fever/shock syndrome is based on a unique mechanism that reflects the virus's evolution into four distinct serotypes.

Yellow fever virus

Despite the existence of a highly effective vaccine since the late 1930s, tens of thousands of cases of yellow fever still occur each year, principally in rain forest regions of west Africa, where the virus is maintained through mosquito passage among wild primates. In the New World, where the virus was carried by the slave trade, it now occupies a similar ecological niche among monkeys in the rain forest of Brazil and adjacent countries. Sporadic cases of yellow fever occur in rural areas where sylvatic mosquitoes carry the virus to forest workers. In contrast, large outbreaks of urban yellow fever can take place when an infected individual travels to a city,

where the virus can be carried from person to person by *Aedes aegypti* mosquitoes. Fortunately, a significant urban outbreak of yellow fever has not occurred for several decades. However, historical records document major urban outbreaks in South America and North America including the southern gulf coast of the United States and as far north as Philadelphia and Boston. The capacity of yellow fever virus to leave its animal host and maintain itself in a human population suggests that its geographic distribution could eventually resemble that of dengue virus, which is found in tropical areas across the world.

As noted earlier, the partial adaptation of yellow fever virus to humans is reflected in a broad spectrum of disease severity, ranging from mild illness to full-blown hemorrhagic fever with hepatic failure and shock. Limited data from patients in west Africa and South America have shown that severe illness is marked by high levels of circulating proinflammatory cytokines, elevated liver enzymes in the serum, and disseminated intravascular coagulation. Patients develop a petechial rash, followed by mucosal and gastrointestinal hemorrhage, renal failure, and shock, leading to death 1–2 weeks after the onset of illness. Treatment is supportive. Although ribavirin inhibits yellow fever virus in cell culture and was protective in a hamster model of infection, it did not alter the course of illness in nonhuman primates.

Prevention of yellow fever is based on a combination of vaccination and mosquito control. The live, attenuated 17D chick embryo vaccine, first used in the field in 1937, is solidly protective against the disease. Travelers to endemic areas must provide evidence of vaccination within the past 10 years. The vaccine is unfortunately employed to only a limited extent in the poor and remote regions of Africa and South America where infection is most prevalent. The major mosquito vector, *A. aegypti*, breeds in collections of water associated with human habitation. It once carried yellow fever as far north as Boston, but aggressive eradication programs eliminated the mosquito and the disease from urban areas of the Western Hemisphere by the early 1930s. The subsequent abandonment of these efforts has permitted the return of *A. aegypti* to these regions, as evidenced by epidemics of dengue fever, but urban outbreaks of yellow fever have not yet reappeared.

Dengue virus

Dengue virus is transmitted from person to person by mosquitoes of the genus *Aedes* in tropical regions across the world, causing tens of millions of infections each year. Although the agent can cause silent infection in various nonhuman primate species, these animals do not play a role as a natural reservoir. It seems likely that dengue fever was at one time a geographically localized zoonosis, similar to yellow fever, but the growth of large tropical cities provided it with the ‘culture flask’ needed for it to evolve into an agent capable of sustained transmission among humans. The spread of dengue virus throughout the tropics has been accompanied by the development of four distinct serotypes that now circulate continuously in Southeast Asia and the Americas. Previous infection with one dengue serotype provides lifelong immunity against that type, but a subsequent infection by a different serotype may result in a severe illness, dengue hemorrhagic fever/shock syndrome.

Probably because of the virus’s history of adaptation to humans, most cases of primary dengue fever amount to no more than an unpleasant flu-like illness. After an incubation period of up to a week, there is an abrupt onset of fever, headache, and muscle and bone pain, reflecting the release of proinflammatory cytokines from virus-infected monocytes and macrophages. A morbilliform rash may be present. Laboratory evaluation shows leukopenia and mild thrombocytopenia, but blood coagulation remains normal. By the time of symptom onset, virus is no longer circulating in the blood, and the illness resolves uneventfully.

A small percentage of dengue patients develop a hemorrhagic fever syndrome, in which the symptoms just described are followed by a fall in blood pressure and coagulation defects that may lead to bleeding and shock. In contrast to the classic dengue, virus is present in the blood after the onset of illness, accompanied by high levels of proinflammatory mediators such as interleukin-6 and tumor necrosis factor- α . Although some of these cases may reflect an encounter with an unusually virulent viral strain, most of them result from a second infection by a different serotype, and are thus a consequence of the genetic heterogeneity of the virus.

Two immune mechanisms appear to be responsible for the occurrence of dengue hemorrhagic fever. First, in a person with a previous history of dengue virus infection, nonneutralizing antibodies in the plasma can enhance the severity of a heterologous infection by binding to circulating virions, then linking them to the surface of monocytes through attachment to surface Fc receptors, leading to fusion and virus uptake. This ‘virion delivery system’ increases the number of infected cells, the number of viral particles that enter each cell, and the magnitude of the resulting cytokine response. Second, cross-reactive memory CD8⁺ T cells remaining from an earlier infection may recognize viral epitopes expressed on the surface of infected monocytes and attack them, triggering an explosive inflammatory response. Both mechanisms increase the release of vasoactive mediators far above that seen in ordinary dengue, causing a hemorrhagic fever syndrome. However, because tissue damage is minimal and adaptive immune responses remain intact, patients who are treated promptly with intravenous fluids can recover within a matter of days.

Efforts to develop effective dengue vaccines have been under way for many years, but field trials have been hindered by the concern that a partially protective vaccine might elicit only nonneutralizing antibodies, rendering subjects susceptible to hemorrhagic fever on subsequent exposure to a natural infection. In the absence of vaccines, prevention efforts include mosquito avoidance, spraying, and destruction of breeding sites. The recent introduction of *A. albopictus*, a vector that can breed in swamp and woodland areas in cooler climates, into the Western Hemisphere has extended the potential range of the disease into temperate regions and made control strategies much more problematic.

Other flaviviruses

The other three flaviviral agents of hemorrhagic fever are more typical zoonoses, in that the viruses are maintained in animals and transmitted to humans within confined geographic areas. Omsk hemorrhagic fever occurs in western Siberia, in the regions around

Omsk and Novosibirsk. The causative agent is maintained in water voles, in which it apparently does not cause illness, but it can cause severe or lethal infection in muskrats, which have recently been introduced to the area. Humans become infected through direct contact with muskrats during trapping or by tick bite, and apparently may also acquire the illness by drinking contaminated water. The virus can also spread to sheep and goats and be transmitted through their milk. The case-fatality rate of Omsk hemorrhagic fever is in the range of 1–3%. The agent shows antigenic cross-reactivity with tick-borne encephalitis virus, so that locally produced vaccines against the latter provide a degree of cross-protective immunity.

Kyasanur Forest disease is found primarily in Mysore State, India, where several hundred cases occur each year. The virus is maintained in rodents and transmitted by *Hemaphysalis* ticks to monkeys and other animals; humans usually become infected through a tick bite. Kyasanur Forest disease generally presents as a flu-like illness but can occur as a biphasic disease with the second phase more severe with occasional evidence of hemorrhage, although this is not a frequent manifestation of the disease. The case fatality rate for Kyasanur Forest disease is around 4% with those recovering from the disease suffering few long-term sequelae. A formalin-inactivated vaccine is licensed for use in India.

Alkhurma (aka Alkhurma) hemorrhagic fever was first identified in abattoir workers in the Saudi Arabian city of Jeddah in the mid-1990s. This virus was initially identified as being among the tick-borne encephalitis serocomplex of flaviviruses and was subsequently shown by genetic analysis to be closely related to Kyasanur Forest disease virus. Infection with Alkhurma virus has been documented in about 50 human cases, primarily in Saudi Arabia. However, evidence suggested that Alkhurma virus may also be found in southern Egypt as reports of two exported cases to Italy indicates that both patients visited camel markets in Egypt. Alkhurma virus has been isolated from *Ornithodoros savignyi* and *Hyalomma dromedarii* ticks in Saudi Arabia suggesting that ticks are the principal vector for this virus.

Vaccines

The 17D yellow fever vaccine is the only vaccine for protection against a hemorrhagic fever virus that is licensed worldwide. However, a number of vaccines are approved for use in individual countries or are currently in clinical trials.

Arenaviruses

Junin virus

The Candid #1 vaccine for protection against Junin virus infection is the only available vaccine for an arenavirus and is only available for use in Argentina. It is a live, attenuated vaccine that was generated through serial passage of wild-type strain XJ 44. The Candid #1 vaccine is well tolerated and Junin virus specific neutralizing antibodies can be detected within 15 days postvaccination with over 95% of vaccinees seroconverting within 60 days of vaccination. Vaccination campaigns in Argentina have significantly reduced the number of cases of Argentine hemorrhagic fever.

Bunyaviruses

Crimean-Congo hemorrhagic fever virus

A vaccine for protection against Crimean-Congo hemorrhagic fever has been in use in Bulgaria since 1974 to protect individuals living or working in endemic areas. This is the only actively used vaccine for Crimean-Congo hemorrhagic fever. This vaccine is an inactivated mouse brain preparation that was originally developed in the Soviet Union in 1970. There is very little clinical use data for this vaccine and its safety and efficacy are unclear. However, reports indicate that there has been a marked decrease in the number of Crimean-Congo hemorrhagic fever cases in Bulgaria since initiation of vaccine efforts.

Rift valley fever virus

The live, attenuated Smithburn strain of Rift Valley fever virus is used in sub-Saharan Africa to prevent or limit outbreaks in livestock. This virus was first reported in 1949 following serial passage of a wild-type virus through mouse brains. While the use of the Smithburn vaccine has met with some success, there are reports of adverse responses, including abortions, in vaccinated animals. The MP-12 vaccine was generated by serial passaging of wild-type virus ZH548 in MRC-5 cells in the presence of the mutagen 5-fluorouracil. The MP-12 has subsequently been tested for safety and efficacy in a number of agricultural species including sheep and cattle. MP-12 has also been shown to protect non-human primates in direct virus challenge studies. A phase II clinical trial assessing vaccine safety and immune response stimulation in human volunteers has also been completed.

Filoviruses

While there are no licensed vaccines for protection against filovirus infection, there are a number of candidates that have shown some promise in animal studies. Perhaps the two leading candidates include an adenovirus-based vaccine that has been tested in several clinical trials in Africa and a vesicular stomatitis virus (VSV) vectored vaccine that has yet to be included in clinical trials. In addition to showing protective efficacy in primate challenge studies, the VSV-based vaccine has also shown potential as a post-exposure option if given shortly after exposure. A third live-virus based vaccine is a recently developed vaccine using the live-attenuated rabies vaccine strain as the vector for a potential “double hit” vaccination against rabies and ebolavirus which would be

beneficial in human and non-human primate populations in Africa. Given the size of the outbreak in West Africa, in late 2014 the adenovirus and VSV vaccines were pushed into phase I and phase II/III clinical trials.

Flaviviruses

Yellow fever virus

The live, attenuated yellow fever vaccine strain 17D was first developed in 1937 and is still in use world-wide. It was generated by extended serial passage origination the original yellow fever virus isolate Asibi. Over 500 million doses of the 17D vaccine have been given with very few instances of vaccine failure or vaccine-associated illness. A single dose of the vaccine provides protective immunity within 10 days postvaccination in nearly all vaccinees and evidence suggests that immunity is life-long. Current recommendations require a booster vaccination every 10 years.

Dengue virus

Development of a vaccine to protect against dengue virus infection has been one of the greatest challenges in virus vaccinology, because dengue virus exists as four distinct serotypes, and epidemiologic studies have shown that antibodies elicited by one serotype may induce enhanced disease upon secondary infection by a different serotype. A successful dengue vaccine must therefore produce protective neutralizing antibody titers against all four serotypes. A number of attenuated virus and recombinant virus or subunit vaccines have been tested over the years with limited success. There are currently several tetravalent dengue vaccines that show considerable promise, but additional clinical trials are necessary.

Kyasanur Forest disease virus and Alkhurma virus

As mentioned above, a formalin-inactivated vaccine is available in India for protection against Kyasanur Forest disease virus. There are also several vaccines available for tick-borne encephalitis virus that are licensed in Europe and Russia. Kyasanur Forest disease virus and Alkhurma virus are both members of the tick-borne encephalitis serocomplex of flaviviruses and share significant amino acid sequence homology with other members of the serocomplex. Although not conclusively proven or disproven, antigenic similarity between viruses within the tick-borne encephalitis serocomplex suggests that the licensed vaccines should provide some level of cross-protection.

Conclusion

The hemorrhagic fever viruses constitute a small subset of the vast number of different viruses that are encountered by humans over the course of life. Adapted through coevolution to persist in animals, these agents are fortuitously capable of replicating to high yield in human macrophages and suppressing type I interferon responses, permitting their rapid systemic dissemination. The resulting release of large quantities of proinflammatory mediators into the circulation causes a syndrome of coagulopathy and vascular collapse resembling septic shock.

Because the host response to hemorrhagic fever virus infection appears to be largely self-destructive, it is tempting to conclude that the human immune system is ill-equipped to deal with microbial threats. In fact, a defensive strategy based on the automatic release of proinflammatory mediators by macrophages whenever they encounter a microbe works well for the majority of infectious processes, which are localized in nature, and fails only when the unrestricted spread of a pathogen causes inflammation to occur 'everywhere at once'. Although the resulting severe illness is a disaster for the affected individual, it may actually benefit the larger population by quickly immobilizing (and often killing) the sick person, reducing the likelihood of further disease transmission. From an evolutionary point of view, inflammatory responses may therefore be seen as a 'double-edged sword', useful both to control minor infections and to hinder the cross-species transfer of novel pathogens.

Glossary

Adjuvant Substance added to a vaccine to help stimulate the body's immune response to the target antigen, by increasing the antibody response and providing longer protection.

Alanine transaminase (ALT, formerly SGPT) An enzyme found predominantly in liver, released into the serum as a result of liver injury. In most liver diseases, ALT is elevated to a greater level than the aspartate transaminase (AST), and in acute viral hepatitis levels of $>1000 \text{ IU mL}^{-1}$ are not uncommon.

Alkaline phosphatase (ALP) An enzyme that is made in the liver, bone, and the placenta and can be measured in serum. It is increased in the setting of diseases in which bile secretion is impaired, and to a lesser degree in association with hepatocellular injury.

Angioedema A skin eruption similar to urticaria but affecting both the dermis and the subcutaneous tissue (deeper skin layer).

Ascites Abnormal accumulation of fluid in the abdominal cavity. Ascites is associated with advanced liver disease complicated by portal hypertension but can be seen in other conditions including abdominal malignancies.

Aspartate transaminase (AST, formerly SGOT) An enzyme found in many tissues including the liver, heart, muscle, kidney, and brain. It is released into serum when any one of these tissues is damaged, for example, after a myocardial infarction or muscle injury. Although not a highly specific indicator of liver injury, levels of $>500 \text{ IU mL}^{-1}$ suggest acute hepatitis.

B cells These lymphocytes mature in the bone marrow and are responsible for humoral immunity.

Bilirubin A chemical that results from the breakdown of red blood cells. Increased levels in serum result from increased red cell destruction (hemolysis), decreased uptake by the liver, or decreased excretion into the bile. High levels in the serum are associated with jaundice.

Cholestasis Caused by obstruction to bile flow within the liver (intrahepatic) or outside the liver (extrahepatic). The obstruction causes bile salts, the bile pigment bilirubin, and fats (lipids) to accumulate in the blood instead of being eliminated normally.

Cirrhosis The final common histological pathway for a wide range of chronic liver diseases, the hallmark of which is the formation of microscopic or macroscopic nodules of normal liver tissue separated by bands of fibrous tissue. Injury to the liver cells results in an inflammatory response that leads to the formation of scar or fibrous tissue. The liver cells that do not die replicate to replace the cells that have died, resulting in clusters of newly formed liver cells (regenerative nodules) within the fibrous tissue.

Cytopathic Pertaining to or characterized by pathological changes in cells.

Cytopenias A reduction in the number of cells circulating in the blood, which can take several forms; anemia is a decrease in red cell count, leucopenia is a decrease in white cells, and thrombocytopenia is a reduction in platelets. When all three classes of blood cells are decreased, the condition is known as pancytopenia.

Cytotoxic T lymphocytes Lymphocytes that mature in the thymus gland and generate cell-mediated immune responses, directly destroying cells that have specific antigens on their surface recognizable by these T cells.

Deoxyribonucleic acid (DNA) The genetic material of all cellular organisms and most viruses. A molecule of DNA consists of two strands composed of nucleotides, linked together to form a chain in the form of a double helix. DNA carries the information needed to direct protein synthesis and replication.

Enteral Entry of a substance or organism (such as a virus) into the body via the gastrointestinal tract.

Epitope Also known as the antigenic determinant, this is the specific part of an antigen that can be recognized by an antibody.

Glomerulonephritis An inflammation of the glomeruli, bunches of tiny blood vessels inside the kidneys. The damaged glomeruli cannot effectively filter waste products and excess water from the bloodstream to make urine.

HBV cccDNA Hepatitis B virus covalently closed circular DNA is a continuous double-chain ring, which serves as the template for all viral RNA transcription.

Hepatic portal system A portal system is a capillary bed draining into another capillary system through veins before returning to the heart. The hepatic portal system refers to the circulation of blood from parts of the gastrointestinal tract, via the hepatic portal vein into the hepatic sinusoids.

Hepatic steatosis One of a spectrum of liver diseases termed nonalcoholic fatty liver disease (NAFLD) that have in common the accumulation of excess fat in liver cells. These conditions range from simple steatosis (excess fat without inflammation), to

[☆]Change History: December 2018. AJ Uriel, P Martin has been updated the abstract, text, and reference.

This article is an update of A.J. Uriel, P. Martin, Hepatitis viruses, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 354–375.

nonalcoholic steatohepatitis (NASH), through to cirrhosis. The term nonalcoholic is used because NAFLD occurs in individuals who do not consume excessive amounts of alcohol, but the appearance of the liver microscopically is similar to that seen in alcoholic liver disease. NAFLD is associated with insulin resistance and the metabolic syndrome.

Hepatomegaly Enlargement of the liver.

Humoral immune response The production of antibodies that circulate through the blood and other body fluids, binding to antigens, and helping to destroy them.

Insulin resistance (IR) The uptake of glucose into tissues is stimulated by insulin, in the setting of IR, tissues have an impaired responsiveness to the actions of insulin. In an effort to maintain normal glucose levels, the pancreas secretes more insulin, leading to high plasma insulin levels. Over time the pancreas is unable to overcome IR through hypersecretion and overt diabetes develops.

International normalized ratio (INR)/prothrombin time These laboratory tests are measures of the extrinsic pathway of coagulation, and are a sensitive method of assessing liver function. The INR is the ratio of a patient's prothrombin time to a normal (control) sample.

Jaundice The yellowish coloration of the skin and sclerae (the whites of the eyes) observed when bilirubin levels are increased above a certain level. Also referred to as icterus.

Lipoprotein Classes of conjugated proteins in which proteins are combined with a lipid (fat) such as cholesterol. These complexes are the form in which lipids are transported in the circulation. Lipoproteins are classified by their density and chemical properties.

Lymphocyte Specialized white blood cells whose function is to identify and destroy invading antigens, are subdivided into B and T cells.

Major histocompatibility complex (MHC) A large cluster of genes located on the short arm of chromosome 6, which is traditionally divided into the class I, II, and III regions, each containing groups of genes with related functions. Many, but not all of the genes in this complex play important roles in the immune system.

Metabolic syndrome This syndrome can be defined as a number of related conditions, including obesity, hypertension, abnormalities of lipid metabolism, and type 2 diabetes, that are associated with IR and compensatory hyperinsulinemia.

Parenteral Entry of a substance or organism (such as a virus) directly into the bloodstream, via a device such as needle or catheter.

Polyarteritis nodosa A disease of unknown etiology, possibly due to hypersensitivity to an unknown antigen, causing inflammation and necrosis of medium-sized muscular arteries, with secondary ischemia of tissue supplied by affected vessels.

Portal hypertension Elevated blood pressure in the portal vein and its branches, resulting from intrahepatic or extrahepatic portal venous compression or occlusion. In the United States and Europe, the commonest cause is increased resistance to blood flow caused by extensive scarring of the liver in cirrhosis. Increased pressure in the portal circulation causes the formation of new veins called collaterals that develop at specific places, most importantly at the lower end of the esophagus and upper part (fundus) of the stomach.

Purpura Hemorrhages in the skin and mucous membranes having the appearance of purplish spots or patches.

Ribonucleic acid (RNA) A molecule of nucleic acid that differs from DNA by containing ribose rather than deoxyribose. RNA is formed on a DNA template. Several differing molecular classes of RNA are produced (messenger, transfer, and ribosomal) that play roles in the synthesis of protein and other cell functions. It reflects the exact nucleoside sequence of the genetically active DNA.

Splenomegaly Enlargement of the spleen.

Transient liver elastography A noninvasive technique for the evaluation of fibrosis in chronic liver disease, transient elastography uses a special probe that consists of an ultrasound transducer array mounted on the axis of a motor vibrator. Liver hardness (or stiffness) is evaluated by measuring the velocity of a vibration wave (also called a "shear wave") generated by the probe placed on the skin overlying the liver. Shear wave velocity is determined by measuring the time the vibration waves takes to travel to a particular depth inside the liver. As fibrous tissue is harder than normal liver, the degree of fibrosis can be inferred from liver hardness.

Urticaria A skin eruption consisting of localized wheals and erythema ("hives") affecting only the dermis (superficial skin layer).

Varices Abnormally enlarged and convoluted veins, prone to bleeding, seen in the lower esophagus and stomach in association with portal hypertension.

Vasculitis A group of diseases in which the primary pathology is inflammation of the blood vessels. Each of these diseases is differentiated by the characteristic distributions of blood vessel and organ involvement, and laboratory test abnormalities. Underlying immune system abnormality is a common feature.

Abbreviations

ALP	Alkaline phosphatase
ALT	Alanine transaminase
Anti-HBs	Hepatitis B surface antibodies
Anti-HCV	Hepatitis C antibody
AST	Aspartate transaminase
Bili	Bilirubin
cccDNA	Covalently closed circular DNA
DAA	Direct acting antiviral
DNA	Deoxyribonucleic acid
EIA	Enzyme immunoassay
EMC	Essential mixed cryoglobulinemia
HAV	Hepatitis A virus
HBcAg	Hepatitis B core antigen
HBeAg	Hepatitis B e antigen
HBIG	Hepatitis B immune globulin
HBsAg	Hepatitis B surface antigen
HBV	Hepatitis B virus
HCC	Hepatocellular carcinoma
HCV	Hepatitis C virus
HDV	Hepatitis delta virus
HEV	Hepatitis E virus
HVR	Hypervariable region
IFN	Interferon
Ig	Immunoglobulin
IgM anti-HAV	Hepatitis A IgM antibody
IgM anti-HBc	Hepatitis B core IgM antibody
IL-12	Interleukin-12
IM	Intramuscularly
INR	International normalized ratio
IR	Insulin resistance
IVDU	Intravenous drug user
LCMV	Lymphocytic choriomeningitis virus
LT	Liver transplantation
MHC	Major histocompatibility complex
NAFLD	Nonalcoholic fatty liver disease
NANB	Non-A, non-B
NASH	Nonalcoholic steatohepatitis
NHL	Non-hodgkin's lymphoma
NRTI	Nucleoside reverse transcriptase inhibitor
ORF	Open reading frame
RBV	Ribavirin
RIBA	Recombinant immunoblot assay
RNA	Ribonucleic acid
SENV	SEN virus
SVR	Sustained viral response
TNF	Tumor necrosis factor
TTV	Torque teno virus

Defining Statement

We discuss the pathogenesis of acute and chronic viral hepatitis, and the structure, replication, epidemiology, and clinical features of each hepatitis virus (A, B, C, D, and E). Current therapies for chronic HBV and HCV, vaccination against HAV, HBV, HEV, and newly identified hepatotropic viruses will also be covered.

Introduction

Hepatitis is a nonspecific term meaning inflammation of the liver (from the Greek *hepar* for liver + *itis* for inflammation) and does not necessarily imply a viral etiology. Many viruses can cause a systemic infection that may involve the liver with an acute hepatitis (e.g., cytomegalovirus, Epstein-Barr virus, and yellow fever virus). Hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis delta virus (HDV), and hepatitis E virus (HEV) are the five hepatotropic viruses responsible for most cases of acute viral hepatitis. HBV, HCV, and HDV can also cause chronic hepatitis, with the risk of progression to cirrhosis, and hepatocellular carcinoma (HCC). HEV has the potential to cause chronic hepatitis, but only in immunocompromised individuals (Table 1).

Before the identification of individual viruses, acute hepatitis was classified by British hepatologist F.O. MacCallum in 1947 as either infectious (transmitted via the fecal-oral route from person-to-person) or serum (acquired from the transfusion of blood and blood products). With the introduction of diagnostic tests in the 1960s and 1970s, HBV and HAV were identified as the major cause of serum and infectious hepatitis, respectively. In 1977, HDV was identified as a defective ribonucleic acid (RNA) virus that is dependent on HBV to replicate. However, not all individuals with acute infectious or serum hepatitis tested positive for HAV or HBV and it was strongly suspected there were additional causative viral agents. Non-A, non-B (NANB) hepatitis was characterized epidemiologically as either parenterally or enterally transmitted until two additional viruses were discovered in the 1980s: HCV and HEV. HCV was identified in 1989 as the major cause of parenterally transmitted NANB, and HEV in 1983 as the major cause of enterally transmitted NANB hepatitis. Some patients continue to have typical signs and symptoms of acute viral hepatitis, without serologic evidence of infection with any of the currently identified hepatitis viruses (non-ABCDE hepatitis).

HAV and HEV are spread via the fecal-oral route, HEV can also be transmitted from mother to baby, and via blood transfusion. HBV, HDV, and HCV are spread predominantly through parenteral exposure; sexual contact and vertical transfer from mother to infant are generally significant routes of transmission only for HBV. Until recently, sexual transmission of HCV was not considered a significant route of infection; however, there is now accumulating evidence that high-risk sexual activity is a potential HCV risk factor for men who have sex with men.

There is wide geographical variation in the prevalence of these agents, with HAV and HEV endemic in developing countries reflecting an absence of safe, clean water supplies. HBV is highly endemic in sub-Saharan Africa and Asia, and it is estimated that about 5% of the world's population are chronically infected.

Common symptoms of acute hepatitis include fever, malaise, and anorexia (decreased appetite) in the "prodromal" period, followed by the onset of dark-colored urine, pale stools, and jaundice. Although the majority will recover completely, a small proportion may develop severe fulminant hepatitis that carries a high mortality (50%) unless the individual undergoes liver transplantation (LT). Fulminant liver failure due to acute viral hepatitis is the most common emergency indication for LT. Chronic HBV and HCV infections are usually asymptomatic, unless there has been progression to cirrhosis when individuals can present with complications such as ascites and bleeding esophageal varices. Chronic HCV-related end-stage liver disease (ESLD) has been the leading indication for LT in the Western world over the past decade, however improvements in HCV therapy have already made an impact in reducing the numbers of candidates requiring LT. Nonalcoholic fatty liver disease, including the more aggressive variant of nonalcoholic steatohepatitis (NASH), is now the most prevalent chronic liver disease worldwide, paralleling the global epidemic of obesity and diabetes. NASH can progress to cirrhosis and ESLD, and is predicted to overtake chronic HCV as the commonest indication for LT within the next few years.

Histopathology of the Liver

Microscopically, the smallest functional anatomical unit of the liver is the "lobule" (Fig. 1). Each lobule consists of a branch of the hepatic vein (terminal hepatic venule) from which "plates" of hepatocytes radiate toward a number of peripheral "portal tracts," each tract composed of a biliary ductule, terminal hepatic arteriole, and terminal portal venule (the portal triad). In acute viral hepatitis, lobular rather than portal abnormalities dominate, whereas in chronic hepatitis changes are observed in the portal and periportal areas. Histological examination of the liver is not generally required in the setting of acute infection. In chronic viral hepatitis, liver histology is useful in assessing disease severity.

Table 1 The major hepatitis viruses

	<i>Hepatitis A</i>	<i>Hepatitis B</i>	<i>Hepatitis C</i>	<i>Hepatitis D</i>	<i>Hepatitis E</i>
Family	Picornovirus	Hepadnae	Flavi virus	Unclassified	Hepeviridae
Genus	<i>Hepatovirus</i>	<i>Orthohepadnavirus</i>	<i>Hepacivirus</i>	<i>Deltavirus</i>	<i>Hepevirus</i>
Genome	RNA	DNA	RNA	RNA	RNA
Main transmission routes	Fecal-oral	Parenteral/sexual	Parenteral	Parenteral	Parenteral/fecal-oral
Materno-fetal transmission	No	High risk	Low risk	No	High risk
Chronicity	No	Yes	Yes	Yes	Yes (in immunocompromised)
Commercially available vaccine	Yes	Yes	No	Prevented by hepatitis B vaccination	No

Fig. 1 The structure of the liver's functional units, or lobules. Blood enters the lobules through branches of the portal vein and hepatic artery, then flows through small channels called sinusoids that are lined with hepatocytes. Reproduced from Cunningham, C. C. and Van Horn, C. G. (2003). Energy availability and alcohol-related liver pathology. *Alcohol Research and Health* 27(4), 281–299, with permission.

Acute Viral Hepatitis

The etiology of an acute hepatitis caused by any of the five hepatitis viruses cannot be distinguished solely by clinical or biochemical features, and requires serological testing. Common prodromal symptoms include malaise and anorexia (loss of appetite), followed by dark-colored urine, pale stools, and icterus (jaundice). Although most cases of acute viral hepatitis resolve uneventfully, some patients with acute HBV and HCV become chronically infected. A minority of patients with acute HAV, HBV, and HDV (and also with acute HCV but far less likely) will develop fulminant hepatitis with acute liver failure. Affected individuals can also be asymptomatic, identified only after the infection has resolved, by positive serology performed incidentally (e.g., before blood donation).

Histology of Acute Viral Hepatitis

The histological picture is similar in acute hepatitis caused by any of the major hepatitis viruses. Characteristic findings include lobular disarray, diffuse hepatocyte injury, ballooning, eosinophilic degeneration, and necrosis, together with a predominantly mononuclear inflammatory response in the parenchyma and portal tracts. The inflammatory infiltrates consist mainly of T-cell lymphocytes, reflecting the role of cellular immunity in the pathogenesis of hepatitis. Although "interface hepatitis," formerly referred to as "piecemeal necrosis" (the destruction of hepatocytes at an interface between liver parenchyma and connective tissue), is the defining feature of chronic hepatitis, it is also seen in acute hepatitis, particularly with HBV. Cholestasis may also be observed. As the reticular framework of the liver is usually preserved in acute hepatitis, hepatocyte regeneration and complete restoration of the liver normally occur after resolution of infection.

Typical features of acute HAV infection include hepatocellular injury and necrosis that predominates around the portal tracts, and a portal and periportal inflammatory infiltrate that contains abundant plasma cells. In adult-acquired acute HBV, histological findings are characterized by severe centrilobular necrosis and inflammation. Portal lymphoid aggregates and bile duct lesions of the Poulson-Christoffersen type are characteristic of acute HCV, occurring rarely in other types of acute viral hepatitis (Fig. 2).

Acute Viral Hepatitis—Pathogenesis

Most hepatitis viruses are non cytopathic, liver damage in the acute as well as the chronic stages reflects the host immune response, largely controlled by CD4 T-helper lymphocytes. These immune responses are directed at viral- or self-antigens expressed on the

Fig. 2 Histological features of (A) acute recurrent hepatitis C in a liver allograft showing diffuse necro-inflammatory changes in the parenchyma with acidophilic bodies, inflammation, and ballooning degeneration of hepatocytes; and (B) chronic hepatitis C with nodular cirrhosis. Courtesy of Dr. S. Thung, Mount Sinai School of Medicine, New York.

surface of infected hepatocytes via the major histocompatibility complex (MHC). In acute HBV, the antiviral cytotoxic T-lymphocyte response is directed against multiple epitopes within the HBV core, polymerase, and envelope proteins. The mechanism of cytotoxic T-lymphocyte destruction of HBV-infected hepatocytes has been investigated in a mouse model, with the number of infected hepatocytes killed by direct interaction between cytotoxic T lymphocytes and their targets insufficient to explain the extent of damage observed in acute hepatitis. It has therefore been postulated that much of the injury is due to secondary antigen-non-specific inflammatory responses induced by the response of the cytotoxic lymphocytes (e.g., due to release of tumor necrosis factor (TNF), free radicals, and proteases), and also possibly due to the involvement of other immune cells such as natural killer T cells.

It is believed that the immune response to one or more viral proteins is responsible for both viral clearance and liver injury during infection.

Acute Viral Hepatitis—Clinical Features

Parenterally transmitted hepatitis viruses tend to have longer incubation periods than those transmitted via the enteric route. An incubation period of between 40 and 160 days is observed in HBV and HDV infection, 15–160 days with HCV, 14–60 days for HEV, and 10–50 days for HAV.

In symptomatic individuals, after a typical viral prodrome, symptoms of anorexia, right upper abdominal discomfort, with dark urine and pale stools, precede the onset of icterus by several days. On examination, the liver is usually enlarged/palpable and mildly tender, although marked hepatomegaly or splenomegaly is uncommon. Once the patient is icteric, fever resolves and constitutional symptoms generally improve. The duration of jaundice can vary from a few days to several weeks. In the majority of cases, acute viral hepatitis is a self-limited disease with patients recovering completely by 2–8 weeks after the onset of jaundice. Occasionally a patient may experience “biphasic hepatitis,” where initial clinical improvement is followed by a relapse of signs and symptoms. This is most often seen in HAV infection; if this situation occurs in a patient with acute HBV, the possibility of acute HDV should be considered. Although wide fluctuations in alanine transaminase (ALT) occurring over weeks to months can be seen in acute HCV, a true “biphasic” course is uncommon. Approximately 10% of subjects with acute HBV initially develop a serum sickness-like syndrome

(characterized by skin rash, angioedema, and arthritis) due to circulating immune complexes of viral particles and antibody with complement activation (see “Extrahepatic Manifestations of Viral Hepatitis”).

Fulminant Acute Viral Hepatitis

The majority of cases of fulminant hepatitis (>50%) are due to acute HBV (with and without HDV superinfection). Fulminant disease is only seen in a small percentage of patients with HAV (this is more likely if the disease is acquired by older adults), and very rarely associated with acute HCV. Between 1% and 2% of cases of HEV can also become fulminant, particularly when acquired by females in the later stages of pregnancy when the percentage increases to over 20%. Individuals with underlying chronic liver disease, such as HCV-related cirrhosis, who are infected acutely with HBV, HAV, or even HEV, are at increased risk for a fulminant course. In patients with chronic HBV, hepatitis flares and rarely fulminant hepatitis can accompany changes in immunological response to the virus, for example, reversion from nonreplicative to replicative infection (hepatitis B e antigen (HBeAg)-to-anti-HBe seroconversion), and can also be seen in individuals with previously quiescent chronic HBV undergoing immunosuppressive or cancer chemotherapy. Although only a small percentage of patients with acute viral hepatitis develop fulminant hepatitis, altered mental status in an icteric patient should prompt referral to a transplant center because of the high mortality rate.

Acute Viral Hepatitis—Laboratory Features and Diagnosis

Acute viral hepatitis can usually be differentiated from other causes of acute jaundice by the marked elevations of two liver enzymes measured in serum, ALT, and aspartate transaminase (AST). ALT is typically higher than AST, but absolute levels correlate poorly with clinical severity. Serum transaminases begin to increase during the prodromal period, preceding the onset of jaundice, and can reach a peak level of $>1000^{\circ}\text{IU}^{\circ}\text{L}^{-1}$ (normal range $10\text{--}40\text{ IU L}^{-1}$). The serum bilirubin (Bili) is mainly conjugated and reflects the severity of the hepatitis; however, large elevations in transaminases can be seen without significant elevations in Bili, particularly in acute HCV. Alkaline phosphatase (ALP) is usually only mildly to moderately elevated, marked elevation suggests extrahepatic cholestasis and should prompt imaging, for example, with ultrasound. Occasionally, there may be a cholestatic phase (most commonly seen with HAV infection) when Bili and ALP levels remain elevated in the face of decreasing transaminases, with the patient exhibiting symptoms of severe pruritis (itching) and jaundice. Assessment of the synthetic function of the liver with albumin and coagulation tests, that is, prothrombin time and International normalized ratio (INR), provides the most sensitive measure of liver injury. Increasing prolongation of the INR implies possible hepatocellular failure and evolution to fulminant hepatitis.

The most useful initial serological tests are hepatitis B surface antigen (HBsAg), hepatitis A IgM antibody (IgM anti-HAV), hepatitis B core IgM antibody (IgM anti-HBc), and hepatitis C antibody (anti-HCV) (Fig. 3). Acute HAV is confirmed by IgM anti-HAV. Acute HBV is indicated by the presence of HBsAg with IgM anti-HBc. Unless there is documented anti-HCV seroconversion after a discrete HCV exposure, such as a needlestick injury, acute HCV can be difficult to diagnose conclusively. Viral replication can be confirmed by the detection of HCV RNA in serum, but does not distinguish acute from chronic infection. If HEV infection is suspected, the diagnosis can be confirmed with serology. Both IgM and IgG anti-HEV can be seen in acute infection.

Fig. 3 Graphical representation of evolution of serological markers in acute hepatitis B infection. Reproduced from Center for Disease Control and Prevention, USA, with permission.

Acute Viral Hepatitis—Treatment

Most cases of acute viral hepatitis resolve spontaneously and require no specific treatment other than supportive care. First line antivirals (Tenofovir or Entecavir) should be considered in acute HBV infection complicated by fulminant hepatitis and liver failure. There is a high-risk of progression to chronicity in acute HCV infection, with up to 75% of those exposed failing to clear the virus. Individuals with detectable HCV RNA in the serum 6 months postexposure are defined as having chronic infection, although a small number may still clear the virus spontaneously after this time. With older treatment regimens using Interferon (IFN), efficacy was much greater when instituted early (within 6 months of exposure), rather than waiting until chronic infection was clearly established. However, newer non-IFN, oral combinations of “Direct Acting Anti-viral” drugs, or DAAs (see “[Therapy of Chronic Hepatitis C](#)” section) have high response rates when used in chronic infection, thus removing the impetus for early therapy. Monitoring for a minimum of 24 weeks before starting DAA therapy is currently recommended, although there is emerging data on the use of short DAA regimens in the acute setting.

Extrahepatic Manifestations of Viral Hepatitis

Extrahepatic manifestations of acute and chronic viral hepatitis are most frequently seen with acute or chronic HBV with immune complex-mediated tissue damage. A “serum sickness”-like syndrome sometimes seen in acute HBV is thought to be due to the deposition of circulating immune complexes of HBsAg-anti HBs in blood vessel walls, leading to the activation of the complement system and depressed serum complement levels.

Other types of immune-complex disease may be seen in chronic HBV, including membranous glomerulonephritis and, rarely, polyarteritis nodosa. Deposition of HBsAg, immunoglobulin (Ig), and C3 has been described in the glomerular basement membrane; membrano-proliferative glomerulonephritis has also been reported with chronic HCV. HBV is implicated in up to 20% of cases of childhood membranous nephropathy.

Essential mixed cryoglobulinemia (EMC), initially associated with hepatitis B, has subsequently been shown to be more frequently associated with chronic HCV (>90% cases). Cryoglobulinaemia is characterized by the presence of Igs in the blood (cryoglobulins), which are precipitated into the microvasculature at low temperatures, and then redissolve at temperatures of 37°C. In EMC, cryoprecipitable immune complexes of more than one Ig class are found in the serum; these immune complexes contain HCV RNA. Clinical features of EMC include arthritis, cutaneous vasculitis (palpable purpura), and occasionally glomerulonephritis. EMC can be associated with overt lymphoproliferative disorders of B-cell lineage. A link between HCV infection and B-cell non-Hodgkin's lymphomas has been observed in epidemiological studies, most strongly with marginal zone lymphomas, with reports of patients with HCV and indolent lymphomas responding to antiviral therapy alone.

A variety of other extrahepatic diseases such as Sjögren's syndrome, autoimmune thyroiditis, porphyria cutanea tarda, and lichen planus have been described in chronic HCV. The mechanism by which HCV causes these extrahepatic diseases is still unclear. These conditions may improve or resolve with therapy directed against HCV.

Chronic Viral Hepatitis

Acute infections with HAV do not become chronic, and therefore there is no risk of long-term liver damage. Although most commonly causing acute hepatitis, HEV can also cause chronic infection in the immunosuppressed, such as the recipients of organ transplants. Acute infection with HBV, HDV, and HCV, however, can become chronic, with persisting viral replication 6 months after initial infection. Chronic infection with HBV occurs most commonly in individuals who acquire the virus perinatally or during early childhood when the immune response is muted, whereas exposure in later life through sexual contact or IV drug use leads to chronic infection in less than 5% of cases. Both viral and host factors are thought to contribute to the high rate of chronicity with HCV infection (~80%), which unlike HBV is not related to age of exposure. Neither HBV nor HCV is predominantly cytopathic; hence, inflammation and injury in chronic infection are probably immune-mediated. Chronic HBV and HCV infections are often asymptomatic, patients may complain of vague right upper abdominal discomfort, and nonspecific symptoms such as chronic fatigue and malaise. The natural history of chronic HBV is complex, but recent data suggest that progression to cirrhosis and HCC is correlated with serum HBV DNA levels and HBV genotype. In HCV, up to one-third of chronically infected individuals, if untreated, will progress over a variable time period (usually 20–30 years) to cirrhosis; however, in contrast to HBV, viral factors such as HCV RNA level and genotype do not appear to influence disease progression. The rate of fibrosis progression in chronic HBV and HCV infections is also dependent on host variables, for example, age, immunogenetics, and alcohol consumption. Once cirrhosis develops, additional manifestations include portal hypertension with bleeding esophageal varices and ascites, and impairment of hepatocellular function. The risk of HCC is also increased in cirrhosis, whatever the underlying cause, although the risk is particularly high if the individual has chronic HBV (relative risk increased by >200). However, unique among most causes of liver disease, HCC can occur in chronic HBV infections in the absence of cirrhosis.

LT in Chronic Viral Hepatitis

There is currently no treatment other than LT to offer individuals with chronic HBV or HCV and advanced liver disease with complications such as portal hypertension and ascites. However, recurrence of the original infection after LT is an important cause of

morbidity and mortality. The early results of LT for HBV were disappointing due to the high rates of graft loss from severe cholestatic recurrent HBV infection. LT became a viable option once hepatitis B immune globulin (HBIG) had been shown to reduce recurrence rates to below 10%, and subsequently the combination of HBIG with an antiviral drug (lamivudine) further reduced recurrence to <5% at 5 years. More recently lamivudine has been superseded by the more potent antivirals Tenofovir and Entecavir, which have a high genetic barrier to resistance and minimal side effects, and are therefore better suited to long-term use. Selected patients, with low viral burden prior to transplant can now be managed with HBIG free prophylactic regimens using these potent antivirals. Individuals with HCV viraemia at the time of LT are at a high risk of recurrent infection, which although variable in severity can result in some individuals progressing to cirrhosis within 3–5 years of transplant. In a large US database (>11,000 patients), 5-year survival rates after LT were reduced in HCV-positive compared with HCV-uninfected individuals (69.9% vs. 76.6%). Before the advent of all oral DAA regimens, there was no effective therapy available to prevent recurrent infection with HCV posttransplant, older IFN based regimens being contraindicated in patients with decompensated liver disease due to toxicity and low rate of response. DAAs have been evaluated in clinical trials in the pre and posttransplant setting, and shown to be well tolerated, with high efficacy. Following viral clearance, long term posttransplant survival of HCV positive recipients can be expected to be comparable with HCV negative recipients.

Histology of Chronic Viral Hepatitis

HBsAg-positive “ground glass” hepatocytes are characteristic of chronic and not acute HBV infection. Identification of cytoplasmic HBsAg is possible with special stains (Shikata orcein or Victoria blue stains) or immunohistochemically. Accumulation of hepatitis B core antigen (HBcAg) in hepatocyte nuclei produces an appearance known as “sanded” nuclei. HBcAg is best identified using immunohistochemical staining. Coinfection with HBV and HDV produces the same histological picture as with HBV alone, but often with a more severe degree of necro-inflammation. Hepatitis D antigen can be visualized using immunohistochemical staining.

Characteristic histological features of chronic HCV infection include dense portal lymphocytic infiltrates, often with lymphoid aggregates and sometimes with follicle formation accompanied by varying degrees of interface hepatitis. Mild degrees of biliary epithelium damage (the “Poulsen lesion”) can also be seen. There is currently no commercial immunohistochemical stain for HCV. Hepatic steatosis can be observed in up to 70% of liver biopsies from individuals with chronic HCV (74% in genotype 3 vs. 50% in non-3 genotype) as compared with up to 18% of patients with chronic HBV infection. The high prevalence is due to a combination of the direct steatogenic effect of HCV (particularly genotype 3) and the prevalence of metabolic risk factors in the HCV population. Steatohepatitis has been shown to enhance fibrosis progression in chronic HCV.

Chronic Viral Hepatitis—Pathogenesis

After acute infection with HBV or HCV, impairment of hepatitis virus-specific T-cell responses can lead to failure to clear the virus, with the establishment of chronic infection. Individuals who spontaneously clear HBV and HCV maintain durable virus-specific CD4⁺ and CD8⁺ T-cell responses that can be easily detected in the blood for decades, whereas those who progress to chronic viral hepatitis typically display narrowly focused and weak HBV- and HCV-specific T-cell responses. Virus-specific T cells in these subjects show reduced proliferation and production of cytokines, and there is reduced cytotoxicity of CD8⁺ T cells. The gradual loss of T-cell function is termed “exhaustion,” and is thought to be secondary to the frequent exposure to a high viral and antigenic load, for example, in chronic HBV, large quantities of HBeAg are secreted into the blood and may be the cause of neonatal T-cell tolerance and in altering the reactivity of HBe-specific CD8⁺ T cells. In HCV, it has been demonstrated that other antigen-specific mechanisms are involved in the downregulation of cellular immune responses, even at low antigen concentrations; for example, recombinant HCV core protein has been shown to downregulate interleukin-12 (IL-12) production by macrophages in vitro.

Reduction of effector T-cell function occurs in the following order: IL-2 production being affected first, then cytotoxicity and the production of TNF- α , with IFN- γ production usually preserved until last. In addition, the functional potential of CD8⁺ T cells can be negatively impacted if help from CD4⁺ cells is reduced or unavailable. Finally, viral mutations (which are more frequent in HCV than in HBV infection) also contribute to CD8⁺ T-cell impairment by affecting the intracellular processing of T-cell epitopes, their binding to major histocompatibility molecules, and the stimulation of T-cell receptors. These mutations also affect recognition by specific antibodies, so that all arms of the adaptive immune response are downregulated.

A small number (<2% per annum) of chronically infected HBV patients spontaneously clear HBsAg and develop neutralizing antibodies. In these individuals, HBV-specific T-cell responses become detectable in the blood just before seroconversion. This implies that latent, immune-mediated clearance mechanisms can become spontaneously activated in chronically infected subjects. It is not known whether such immune responses can be induced therapeutically by vaccination and/or antiviral therapy in patients with chronic HBV. Studies in animal models of related chronic viral infections (e.g., the mouse model of chronic infection with the 1 hepatotropic lymphocytic choriomeningitis virus, LCMV) suggested that proliferative CD8⁺ T-cell responses can be partially restored if viral load was reduced with antivirals before vaccination. However, results of studies of HBV peptide and protein vaccination in adults and children with HBV have been disappointing, and although therapy with nucleoside analogs results in a transient recovery of HBV-specific CD4⁺ and CD8⁺ T-cell function in peripheral blood, this does not persist for greater than 6 months. Antiviral therapy in chronic HCV is not associated with even a transient increase of HCV-specific T-cell responses. Extrapolating on data obtained from the LCMV-infected mouse model, it would appear that virus-specific CD8⁺ T cells develop an intrinsic defect during chronic infection that prevents a vigorous proliferative response to vaccination even if the virus is removed.

HAV

HAV is a nonenveloped positive-strand RNA virus transmitted via the fecal-oral route. Although globally distributed, risk of infection decreases as levels of hygiene and sanitation improve, and an effective preventative vaccine is available.

Virology

First visualized by immune electromicroscopy in 1973, HAV has been classified within a separate genus of the *Picornaviridae* family, the genus *Hepatovirus* (Fig. 4). The virus is nonenveloped, with a diameter of 27–32 nm, with a linear RNA genome. The 3'-end terminates with a poly (A) tail of 40–80 nucleotides. The genome contains a single, large open reading frame (ORF), which codes for a large polypeptide and which is subsequently cleaved by a viral protease, forming three capsid proteins and several nonstructural proteins. The capsid is composed of 60 copies of each of three major structural proteins, VP1, VP2, and VP3.

Once the virus enters the hepatocyte, there is loss of the protein coat releasing the positive-sense RNA strand into the cytoplasm. Genomic replication takes place by a mechanism involving an RNA-dependent RNA polymerase. HAV then enters the biliary tract and exits the body via the feces. Several viral genotypes have been identified, but with only one serotype, with one immunodominant neutralization site, a property that facilitated the development of an effective vaccine.

Epidemiology

HAV is transmitted via the fecal-oral route, by ingestion of contaminated food or water or direct person-to-person transmission; it can occur either sporadically or in large outbreaks. The highest prevalence of this infection occurs in countries with lack of access to clean water supplies. In endemic areas, infections occur early in life, such that most children by the age of nine are seropositive for HAV. In contrast, HAV is mainly a disease of adults in most industrialized nations, who are much more likely to have symptomatic infection. Despite high seroprevalence rates in highly endemic populations, HAV perpetuates in these regions due to its ability to survive in the environment for prolonged periods, and, once ingested, to withstand the acid environment of the stomach. Food and water can become contaminated with HAV by the use of human feces as fertilizer, and the pollution of water supplies by raw sewage. Consumption of raw or undercooked shellfish is associated with infection as certain mollusks can concentrate HAV from polluted waters. Parenteral transmission of HAV is possible, with cases reported in intravenous drug users, hemophiliacs, and rarely via blood transfusion. Sexual oro-anal contact can also result in transmission. Recent data indicates that the global epidemiology of the disease is changing, mainly due to improvements in living conditions in developing countries, with fewer children becoming infected. This results in a larger population of adults without protective antibodies who are at risk of symptomatic infection. In Europe and the United States, outbreaks of HAV have been described in men who have sex with men (MSM), and there have also been large food-borne outbreaks recently reported associated with consumption of contaminated frozen berries and soft fruit.

Clinical Features

The incubation period is from 10 days up to 7 weeks, during which time high levels of HAV are present in liver tissue, bile, and feces (virus can also be detected in blood in lesser amounts); the infected individual is generally asymptomatic and highly infectious. After the 4th or 5th week of infection there is an immune response accompanied by the first symptoms (the prodromal or preicteric period), which may include fatigue, fever, anorexia, nausea and vomiting, diarrhea, and right-sided abdominal pain. During this

Fig. 4 Electron micrograph of hepatitis A virus particles. Reproduced from Center for Disease Control and Prevention, USA, with permission.

period, ALT and AST are increasingly elevated. Generally, within 10 days of the onset of symptoms the patient enters the icteric phase of infection, with resolution of fever and marked decrease in viremia, although virus is still shed in the feces for another 1–2 weeks. Extrahepatic symptoms are uncommon, although urticaria can occur. Jaundice usually resolves over 1–2 weeks, and a complete recovery can take up to 6 months. The neutralizing antibodies produced in an infected individual can be used therapeutically to prevent infection in an exposed individual (hyperimmune or γ -globulin).

Diagnosis

Routine diagnosis is usually made by the detection of IgM anti-HAV. Experimentally, infection with HAV can be confirmed by the detection of virus in the blood or feces. Antibodies to HAV of the IgM class can be detected approximately 3 weeks after exposure, and these increase in titer over the next 4–6 weeks before disappearing from the blood. Shortly after the appearance of IgM anti-HAV antibodies, IgG anti-HAV antibodies can be detected; these persist for years after resolution of acute infection, conferring lasting immunity. As the presence of IgG anti-HAV in the serum can indicate either prior or current infection, it is therefore important to request both IgM anti-HAV and IgG anti-HAV to establish the diagnosis of acute HAV.

Vaccines

There are four inactivated commercial vaccines currently available for the prevention of HAV. These are safe, highly effective, and provide long-term protection (for at least 20 years) against infection; however, a booster vaccination after 10 years is recommended. Although generally used preexposure, mass postexposure vaccination has been successfully utilized to contain the spread of HAV in established outbreaks. Dosing schedules vary, but generally two doses of vaccine are administered intramuscularly (IM) 6 months apart. This will produce protective levels of antibody within 1 month of the first dose in almost 100% of those vaccinated. These vaccines can be coadministered with others, including live attenuated vaccines, without affecting immunogenicity.

Vaccination strategies differ between areas of high and low endemicity. In most developing countries, HAV is acquired in early childhood and tends to be asymptomatic, and therefore HAV is not a major public health issue requiring universal immunization. As nations develop public sanitation, the age at which individuals will become infected is delayed until adulthood, and subsequently the risk of symptomatic illness is much higher. In such countries, groups at high-risk of infection due to lifestyle or occupation, and travelers to areas of high endemicity, are targeted for vaccination. One study from Ireland showed that if HAV immunity in a population is greater than 45%, screening followed by vaccination of nonimmune individuals is the most cost-effective strategy; if less than 45%, vaccination without prior screening should be used.

Ig

This is more often used in the setting of postexposure prophylaxis or in situations where immediate protection is required. Nonimmune individuals should be given 0.02 mL kg^{-1} of Ig within 2 weeks of exposure, in which case it will either prevent or attenuate the severity of the infection. Ig can safely be given to children, pregnant, and lactating women, and the immunocompromised, and a single dose of 100 IU given IM will provide protection for up to 6 months. Ig should not be coadministered with live attenuated vaccines as this may interfere with the immune response to these vaccines, but can be given with HAV vaccine (at a different site) for maximal protection after an exposure.

HBV

Uniquely among DNA viruses, HBV replicates within infected hepatocytes through a process called reverse transcription. Infection with HBV can result in different clinical scenarios, ranging from fulminant hepatitis to asymptomatic chronic infection, cirrhosis, or HCC. Integration of HBV viral DNA into the hepatocyte nuclear DNA is a key event in hepatocarcinogenesis. HCC resulting from chronic HBV is one of the most common malignancies worldwide.

Virology

HBV is a member of the family Hepadnaviridae, with a double-stranded circular DNA genome that replicates through an RNA intermediate. Although HBV infects only human and higher primates, related viruses are common in rodent (e.g., woodchuck) and bird species (e.g., duck). Hepadnaviridae preferentially infect liver cells, with trace amounts of HBV DNA found in kidney, pancreas, and mononuclear cells without causing disease at these sites. HBV DNA does not integrate into host cellular DNA as part of the viral replication cycle, but may persist in the host cell for many years even after clinical resolution of infection. During this time, HBV DNA may be integrated into cellular DNA and it is thought that integration plays a role in the subsequent development of HCC.

Each HBV particle consists of a 3.2-kb double-stranded circular DNA genome and DNA polymerase enclosed by a viral envelope, containing three related surface proteins, and an icosahedral nucleocapsid of approximately 30 nm diameter.

HBV replication proceeds through a unique and complex mechanism utilizing an RNA intermediate, with viral RNA transcripts being generated from a covalently closed circular DNA (cccDNA) transcriptional template found in the nucleus of the host cell in the

form of a viral mini chromosome. The genome encodes four ORFs, which when translated produce the precore and core, polymerase, small, medium, and large envelope proteins, and the transcriptional regulator protein X. The core gene can also produce a small-molecular-weight protein called HBeAg by an alternate start codon and post-translational modification. The HBV polymerase has a number of functions in the viral life cycle, including the initiation of minus-strand DNA synthesis (priming), the synthesis of DNA using either RNA or DNA templates (polymerase activity), the degradation of the RNA strand of RNA–DNA hybrids (nuclease activity), and the packaging of the RNA pregenome into nucleocapsids.

There are eight HBV genotypes (A–H) so designated on the basis of a genomic variation of at least 8%. Coinfection with different genotypes has been reported. Genotype A is the most widely distributed, being frequent in northwest Europe, sub-Saharan Africa, India, and North, Central, and South America; B and C are common in Southeast Asia and Oceania, and D is prevalent around the Mediterranean, Central Asia, and South America. Genotype E is found only in West Africa, F is limited to Central and South America but is also found in Native Americans, G has been described in the United States and France, and H in Central America.

There is accumulating evidence that HBV genotypes may influence HBeAg seroconversion rates, mutational patterns in precore and core promoter regions, and the clinical severity of liver disease. For example, infection with genotype A HBV may be more likely to become chronic, but causes milder liver disease than other genotypes; it also has a better response to treatment with IFN. In contrast, genotype C HBV appears to be associated with a more aggressive clinical course and faster progression to cirrhosis. The predominant mutation in the precore region of the HBV genome, which completely aborts the production of HBeAg, is rarely seen with HBV genotypes A and F, but is found mainly in genotypes B–D.

The lifecycle of HBV begins with viral attachment and entry into the hepatocyte followed by internalization. Recently, there have been advances in the understanding of this process following the identification of sodium taurocholate cotransporting polypeptide (NTCP) as a cellular entry receptor. Once in the cytoplasm, viral uncoating occurs and HBV DNA is transported to the nucleus where it is converted to cccDNA, a stable template for transcription of both subgenomic messenger RNA (for translation into viral proteins) and pregenomic RNA (for reverse transcription into genomic DNA). HBV cccDNA is responsible for viral persistence. After binding of the HBV polymerase and core Ag to the pregenomic RNA, encapsidation occurs. Synthesis of the negative DNA strand by reverse transcription and partial synthesis of the positive-strand is performed by HBV polymerase within the nucleocapsid, which is then either transferred to the endoplasmic reticulum where it assembles with HBsAg molecules to form the virion, or returns to the nucleus to amplify the cccDNA reservoir. The intact virion exits the cell by budding and vesicular transport. The surface proteins can also bud in the absence of capsids, forming both spherical and tubular (or “filamentous”) particles approximately 22 nm in diameter consisting of HBsAg and host cell-derived lipids (Fig. 5). These particles are also secreted into the blood, as they do not contain viral nucleic acid and they are not infectious, but are highly immunogenic.

The turnover of virions is high, with estimates in the order of 10^{11} virions produced per day—much higher than that for other DNA viruses, HCV, or HIV. The HBV DNA polymerase does not have proofreading or editing capacity, and this together with the high rate of virion production makes replication errors inevitable. It has been calculated that over the period of 1 day, an estimated 10^{14} nucleotides are replicated, with the potential for 10^7 base pairing errors.

The consequence of this high mutational rate is the formation of a large pool of “quasispecies” with the virus, with the best replicative “fitness” becoming the dominant species. Selection pressure, either from the host immune response or from antiviral therapy, can result in vaccine/Ig escape mutants and drug-resistant variants.

Mutations of the HBV envelope, precore, core, and polymerase regions occur. Several precore mutations have been identified in HBeAg-negative patients. The most common mutation observed is a G→A substitution at nucleotide 1896 (G1896A) in the precore region, creating a premature stop codon. Translation of the precore protein is prevented, which aborts the production of HBeAg.

Epidemiology

There are an estimated 350 million people in the world with chronic HBV, with prevalence varying widely between geographical areas. HBV is efficiently transmitted horizontally by intimate contact, by parenteral exposure as well as vertically from mother to infant. However, in about a one-third of adults with acute infection, no risk factors are identified, probably reflecting HBV's ability to survive outside the body for up to a week as well as its ubiquitous presence in body fluids. Vertical transmission occurs peripartum or in infancy rather than in utero. The risk of vertical transmission is increased if the mother is HBeAg-positive with high serum HBV DNA.

Countries with low prevalence in the general population (i.e., carriage rates of HBsAg of less than 2%) include the United States, Canada, Northern, Western, and Central Europe, and Australia; however, within these countries higher prevalence rates are seen in high-risk populations, for example, in intravenous drug users (IVDUs) and in individuals with multiple sexual partners. Intermediate carriage rates (2%–8%) are observed in Eastern Europe, the Mediterranean, Russia and the Russian Federation, Southwest Asia, and Central and South America. The highest prevalence of HBsAg positivity (8% and above) occurs in China, Southeast Asia, Alaska, and tropical Africa. The age at which most HBV transmission occurs varies according to the prevalence rate. The majority of individuals with chronic HBV in countries with high prevalence of HBV acquire infection vertically or horizontally during early childhood. In low prevalence areas, the highest incidence of infection occurs in teenagers and young adults, reflecting sexual and parenteral transmission. Iatrogenic transmissions from contaminated blood transfusions, use of unsterile needles for injections, or vaccinations remain risk factors in the less-developed world.

Clinical Features

Acute infection

The incubation period for HBV infection ranges from 6 weeks to 6 months. Clinical presentation reflects host age and immune status of the host. Acute perinatal or childhood infection is generally asymptomatic. Children older than 5 years and adults are symptomatic in 33%–50% of infections with typical signs and symptoms of acute hepatitis. Fulminant hepatic failure occurs in approximately 1% of patients with acute HBV. Most adults with acute HBV recover completely without sequelae, although in $\leq 5\%$ infection persists into chronicity.

Chronic infection

The natural history of chronic HBV is dynamic, with several phases characterized by differing levels of serum ALT, HBeAg, and HBV DNA. Chronic HBV acquired in infancy or in early childhood often has a prodromal “immune-tolerant phase,” which can last up to young adulthood, characterized by HBeAg positivity, high levels of serum HBV DNA, but with normal levels of ALT and minimal inflammation on liver biopsy. In the late teens or early adulthood, a transition occurs to a more active phase of “immune clearance,” during which time serum HBV DNA levels fall with increasing ALT levels and worsening liver inflammation (classic HBeAg-positive chronic HBV). This phase of active replication is usually asymptomatic, but can be prolonged, with ultimate progression to cirrhosis, although it ends in HBeAg-to-anti-HBe seroconversion at a rate of approximately 10%–15% of individuals per annum. Increased immune responsiveness can be accompanied by an abrupt “flare” in ALT levels, which may even mimic fulminant hepatitis. The third phase, “low-replicative” or inactive carrier state, is characterized by detectable HBsAg and anti-HBe, the absence of HBeAg, and low ($<10^5$ copies per mL) levels of HBV DNA, with a reduction in necro-inflammation on biopsy. However, spontaneous reactivation, with an increase in markers of disease activity (HBV DNA and ALT) without the reappearance of HBeAg, occurs in up to a one-third of individuals (classic HBeAg-negative chronic hepatitis B) owing to mutations in the HBV genome, which abolish HBeAg production but allow a return of HBV replication. HBeAg-negative chronic HBV is characterized by fluctuating ALT levels and progressive liver injury and reflects a later stage of the disease.

Diagnosis of HBV Infection

There are a number of laboratory tests that can be used to diagnose hepatitis B infection, and also to determine whether the individual is in the acute or chronic phase (Table 2).

Therapy of Chronic HBV Infection

Achieving a “cure” in chronic HBV infection with currently licensed therapies is uncommon, due to the persistence of viral DNA in the form of cccDNA within the nucleus of infected hepatocytes. Even individuals achieving clearance of HBsAg with seroconversion to anti HB s are at risk of viral reactivation if they receive prolonged therapy with immunosuppressive agents such as CD20 antibodies (e.g., Rituximab) or high dose steroids. Therefore, the goal of current HBV therapy is to suppress viral replication with the aim of preventing progressive liver disease and the development of complications such as cirrhosis and HCC. Large, prospective, cohort-based studies following a large Taiwanese population of HBsAg-positive patients for a median of 11 years have concluded that serum HBV DNA level is a key predictor of progression to cirrhosis and HCC, independent of ALT and HBeAg status. In 2004, a landmark study from this Taiwanese cohort was the first to demonstrate that an oral antiviral (lamivudine) could suppress HBV replication and modify the natural history of chronic HBV in individuals with advanced liver fibrosis or cirrhosis. In comparison to

Table 2 HBV serology and interpretation of diagnostic tests

Test	Acute HBV	Past exposure (immunity)	Previous immunization	Chronic HBV infection (HBeAg ⁺)	Chronic precore mutant (HBeAg ⁻)
HBeAg	+	—	—	+	—
Anti-HBe	—	—/+	—	—	+

patients receiving placebo, a significant reduction in the rates of hepatic decompensation and HCC was observed in the cohort receiving lamivudine.

The decision as to which individuals with chronic HBV should be treated, which therapy to use, and when treatment should be initiated can be complex, and is outside the scope of this article, however, in general, the most important criteria used are levels of HBV DNA and ALT, and the degree of liver necro-inflammation and fibrosis. Treatment guidelines from the United States and Europe differ slightly in the threshold of HBV DNA and ALT used to initiate therapy, and recommendations also depend on whether the individual is eAg-positive or negative. Increasingly, elevated serum HBV DNA is being proposed as the major criteria to initiate antiviral therapy. Although depending on patient characteristics different thresholds for HBV DNA and ALT may be relevant, in general, noncirrhotic individuals with chronic HBV, elevated ALT, and HBV DNA levels of $\geq 20,000$ IU mL⁻¹ in eAg-positive disease and ≥ 2000 IU mL⁻¹ in eAg-negative disease (>2000 IU mL⁻¹ for both eAg-positive and negative individuals in European guidelines) should be offered treatment if there is evidence of moderate to severe necro-inflammation and/or at least moderate fibrosis on liver biopsy or validated noninvasive marker of fibrosis (such as transient liver elastography). Most authorities would recommend that individuals with cirrhosis or family history of HCC should be considered for treatment regardless of level of HBV DNA or ALT, as frank hepatic decompensation may occur with a spontaneous flare in cirrhotics. A number of end points are used to assess treatment response, normalization of elevated ALT (biochemical), achieving undetectable HBV DNA in the serum using a sensitive assay, and/or loss of HBV surface and eAg (virological), and improvement in liver necro-inflammation and fibrosis (histological).

Seven agents have been licensed for the management of chronic HBV: IFN- α 2b, pegylated IFN- α 2a, and the oral antivirals lamivudine, adefovir, telbivudine, entecavir and tenofovir, although only peg-IFN- α 2a, tenofovir and entecavir are currently considered “first line” drugs. IFN- α has been used to treat chronic HBV since the mid-1980s. A longer acting formulation, pegylated interferon (peg-IFN) has superseded standard IFN since 2005 when Peg-IFN- α 2a was approved for use in chronic HBV. Whereas IFN is contraindicated in individuals with decompensated cirrhosis, the oral agents have the advantage of being safe and well tolerated in this patient population. Efficacy of IFN therapy is strongly dependent on HBV genotype in eAg-positive disease, with best results seen in genotype A and B infections. The advantage of IFN is its finite duration of treatment (48 weeks), absence of selection of HBV resistance mutations, and potential for more durable response, however it has a large number of potential side effects. Lamivudine, a nucleoside analog reverse transcriptase inhibitor (NRTI), was originally developed for the treatment of HIV infection, but was found to also inhibit the replication of HBV and was subsequently licensed for use in chronic HBV in 1998. NRTI's interfere with viral replication by causing premature termination of the DNA chain; other recently licensed members of this drug class include entecavir and telbivudine. Adefovir, introduced in 2002, also works by DNA chain termination but is a nucleotide analog. Tenofovir, a structurally similar nucleotide to adefovir, but with higher potency, was licensed for use in patients with HBV in 2008, having been previously approved to treat HIV infection in 2001. The development of resistance to antivirals such as lamivudine, adefovir and telbivudine with prolonged use has previously been an area of concern, recalling the situation seen in the early days of antiretroviral therapy for HIV, and strategies to address this issue, such as the use of two antivirals from different drug classes (i.e., a nucleoside plus a nucleotide analog) have been evaluated. However as tenofovir and entecavir, which are more potent and have a much higher threshold for resistance, are now considered the preferred options for oral HBV therapy (and have largely replaced earlier agents such as lamivudine) this issue is no longer relevant. In large scale registration trials with long-term follow up less than 1% of patients on entecavir have developed mutations associated with viral breakthrough, and there have been no clinically significant resistance mutations detected in patients treated with tenofovir. There is a commercially available test that detects the key genotypic mutations in HBV polymerase associated with resistance to lamivudine, adefovir, and entecavir. Individuals with HBV who have developed resistance to lamivudine can be successfully treated with tenofovir.

Although these drugs effectively suppress HBV replication, they have much less effect on clearing the “reservoir” of cccDNA in hepatocytes and viral relapse will usually occur once therapy is discontinued. In selected individuals with eAg-positive chronic HBV who achieve seroconversion with the loss of eAg and production of anti-HBe maintained for at least 12 months, an attempt at discontinuation of antiviral therapy can be made, with low chance of relapse. In patients with eAg-negative disease, it is impossible to recognize a treatment-induced seroconversion, and therefore therapy may need to be continued indefinitely. HBs Ag levels are a

surrogate marker for cccDNA and there is evolving data on the use of quantitative HBsAg levels as an aid to predict response to therapy with Peg-IFN. In a recent study by Marcellin et al., on treatment HBsAg decline during peg-IFN therapy was significantly associated with sustained immune control and HBsAg clearance in a cohort of eAg-negative patients. Rates of HBsAg clearance 5 years post IFN therapy were highest in patients achieving at least a 10% decline in sAg levels at weeks 12 and 24 of treatment as compared to baseline. There are ongoing studies on whether HBsAg levels may also be useful to determine when individuals on long-term nucleos(t)ide therapy may be able to be discontinued therapy without risk of relapse.

In recent years there has been a resurgence of interest in the development of potentially curative agents for chronic HBV. Broadly speaking, new therapies can be divided into the following classes; immune modulators, inhibitors of gene expression and replication, cccDNA targeting drugs, and drugs blocking entry of HBV into the hepatocyte.

There are over 30 novel therapies currently in clinical development, the detailed discussion of which is outside the scope of this article. Immunomodulatory agents aim to restore an appropriate immune response to the virus. Specific T and B cell responses to HBV are crucial for elimination of the virus and the cccDNA “reservoir,” and one approach is to target the adaptive immune response, through stimulation via therapeutic vaccines and toll like receptor 7 agonists, and blockade of immune inhibitory pathways. Viral targets other than HBV polymerase in the life cycle have been identified (see Fig. 6) and are the focus of new drug development, such as capsid inhibitors, which interrupt HBV replication via blocking pregenomic RNA encapsidation. This initial stage of the HBV lifecycle has gained attention as a potential target for inhibition following the identification of NTCP as a cellular entry receptor. There are currently a number of NTCP inhibitors in development, including Myrcludex-B, which has shown promise in preclinical studies, and has now progressed to phase 2 clinical trials. It is likely that future approaches to HBV eradication will involve the use of “combination therapy,” using agents from different classes.

Vaccines

Several preventative HBV vaccines are currently available; these rely on the use of one of the viral envelope proteins (HBsAg) and are now made using recombinant technology. HBV vaccines are available in monovalent formulations and in combination, for example, with HAV vaccine. Two recombinant vaccines are available; both are safe, even during pregnancy. Three 1.0 mL IM injections are given into the deltoid or anterolateral thigh, at time 0, 1, and 6 months, although there is flexibility and an accelerated schedule can be used. Children are given lower doses (0.5 mL), and immunosuppressed patients and patients on hemodialysis are given higher doses.

Immunization strategy varies depending on the level of endemicity, with the ideal goal being universal childhood vaccination. Additional strategies include prevention of perinatal HBV infection through routine HBsAg screening of all pregnant women, with immunoprophylaxis given to all babies of HBsAg-positive mothers. As soon as possible after delivery, the infant is given 30 IU of HBIG and an HBV vaccination course is started. Even with prompt administration of HBIG and vaccine, there is still a risk of

Fig. 6 Simplified schema of the hepatitis B virus life cycle and possible targets of therapy. *HBV*, hepatitis B virus; *cccDNA*, covalently-closed circular DNA; *HBsAg*, hepatitis B virus surface antigen; *rcDNA*, relaxed circular DNA; *siRNAs*, small interfering RNAs. From Tajiri et al. “New Horizon for radical cure of chronic hepatitis B virus infection.” *World Journal of Hepatology*.

transmission to the neonate; this risk is increased if the mother is HBeAg-positive and has HBV DNA levels $>10^7$ IU mL⁻¹. In countries with low or intermediate endemicity, a higher proportion of chronic HBV is acquired by older children and young adults, and “catch-up” vaccination for those who were not vaccinated at birth should be considered, particularly for individuals at increased risk for exposure to HBV, such as healthcare workers and persons engaging in high-risk sexual activity.

HCV

HCV is a parenterally transmitted RNA virus, a characteristic feature of which is a propensity to cause chronic infection, with only 15%–20% of acutely infected individuals clearing infection spontaneously. This is explained in part by the extreme genetic diversity of HCV, a feature it shares with other RNA viruses. HCV was first identified in 1989, although clinically its existence had been suspected for many years as the agent responsible for parenterally transmitted “NANB” hepatitis. HCV is globally distributed, with over 170 million individuals estimated to be infected. Decompensated cirrhosis secondary to chronic HCV is still currently the leading indication for LT worldwide, although this is likely to change given that more effective antiviral therapy is now available.

Virology

HCV is a small enveloped positive-sense, single-stranded RNA virus, which is classified as a member of the family *Flaviviridae*, genus *Hepacivirus*. Within an infected individual, HCV exists as a population of closely related yet distinct “viral quasiespecies,” which may differ with respect to replicative capacity, cell tropism, immunologic escape, and antiviral resistance. HCV has six known genotypes (1a/b, 2b, 3a, 4, 5, and 6) and at least 30 subtypes with differing geographical distributions. Genotypes 1, 2, and 3 are distributed worldwide, genotype 4 is found in the Middle East and Africa, genotype 5 in South Africa, and genotype 6 is the predominant genotype in Southeast Asia. Coinfection with more than one genotype is not infrequently seen, and “superinfection” has been reported.

The genome of HCV contains a single, large ORF flanked by 5′- and 3′-untranslated regions, which codes for a polyprotein of approximately 3000 amino acids, which, when cleaved by viral and host peptidases, produces a number of functional proteins, namely three structural proteins, core, and two envelope glycoproteins (E1 and E2), six nonstructural proteins (NS2, NS3, NS4A, NS4B, NS5A, and NS5B), and a protein (p7). The viral nucleocapsid comprises multiple copies of the core proteins in complex with genomic RNA (Fig. 7). Apart from humans, HCV infects only chimpanzees, and characterization of the molecular mechanisms involved in viral replication and immune response to HCV was until recently impeded by the lack of a good in vitro model. Alternative tissue culture systems have now been developed, including recombinant HCV envelope glycoproteins, HCV-like particles, HCV retroviral pseudoparticles, and, most recently, cell culture-derived infectious HCV. Although these models have certain limitations, they have greatly advanced the understanding of the early steps of viral infection and host-virus interactions, and have facilitated the development of several new classes of antiviral drugs specific for HCV.

Circulating HCV is physically associated with lipoproteins or antibodies. The major target cell is the hepatocyte, but it is thought that HCV may be able to infect other cells, such as lymphocytes, monocytes, and dendritic cells. Both E1 and E2 are essential for entry into the host cell. Within the E2 envelope, glycoprotein sequence hypervariable regions (HVR) have been identified, which differ more than 80% among HCV genotypes, and within subtypes of any one genotype. HVR-1 is a HVR that is important for host cell recognition and attachment. A number of potential entry receptors have been identified, including the tetraspanin CD81, scavenger receptor class B type 1 (SR-B1), heparin sulfate, low-density lipoprotein receptor, and, most recently, claudin-1, a protein involved in the maintenance of cell structures called “tight junctions” found in several epithelial tissues and most prevalent in the liver. Binding of viral envelope glycoproteins to the hepatocyte cell surface triggers endocytosis of the HCV virion, and the viral nucleocapsid enters the cytosol and is transported to the endosome where uncoating, IRES-mediated translation, and RNA replication occur. The viral RNA is translated into a polyprotein which is cleaved by both host and viral-encoded proteases into 10 mature viral proteins, including the nonstructural (NS) proteins (see Fig. 7). Synthesis of new viral RNA occurs in a highly structured replication complex that consists of NS3, NS4A, NS4B, NS5A, and NS5B. NS5B is an RNA-dependent RNA polymerase that is essential for viral replication, NS5A has a presumptive role in the organization of the replication complex. One of the viral proteases involved in posttranslational processing is a heterodimeric complex of the NS3 and NS4A proteins (NS3/NS4A). NS3 possesses the proteolytic activity and NS4 is a membrane protein that acts as a cofactor. The serine protease and RNA polymerase enzymes have been the focus for the successful development of a large number of oral antiviral agents, and inhibitors of the NS5A protein are also being studied. Once fully elucidated, entry receptors will also provide an important additional target.

Epidemiology

HCV infection is endemic in most parts of the world, with an estimated overall prevalence of 3%. The virus is predominantly transmitted via the parenteral route, although vertical and sexual transmission is recognized. In about 10% of cases, a source of infection cannot be identified. HCV has been shown to remain viable on surfaces outside the body for up to 16 h, and transmission may occur through sharing of toothbrushes or razors contaminated with infected blood.

Before the introduction of serological tests for HCV, infection with contaminated blood or blood products was a frequent source of infection. Use of contaminated pooled clotting factors led to prevalence rates of over 80% in the hemophiliac population in the

Fig. 7 Structural and genomic organization of the hepatitis C genome. Reproduced from Expert Reviews in Molecular Medicine, 2003, Cambridge University Press.

West, many of whom were also infected with HIV. Following the introduction of screening of blood donors for infection, the risk of transmitting HCV by blood products is presently at 1/200000 units distributed. Transmission from nonsterile injecting practices in healthcare settings is no longer a significant risk for acquisition of HCV, although sporadic cases have been reported in association with poor disinfection procedures for invasive medical equipment such as colonoscopes. HCV has been transmitted through tattooing and body piercing in establishments reusing needles between clients, and rarely infection has been reported to have contracted through manicures and pedicures. In developed countries, IVDUs are currently the only group at significant risk for acquiring HCV. Prevalence rates of HCV approach 80% in the IVDU population, with most becoming infected within 1–2 years of embarking upon intravenous drug use. Incidence of new infections can be reduced by harm-minimization strategies such as needle exchange programs. Health professionals are at risk following needlestick exposures from an infected source, as there is no equivalent of HBV Ig, and currently no vaccine is available.

Vertical transmission is uncommon (seen in <5% cases), the risk is proportional to the maternal HCV RNA level, with higher levels carrying greater risk. Higher HCV viral loads are usually seen in individuals coinfecting with HIV, and increased rates of vertical transmission are seen in HIV-positive mothers.

The role of sexual transmission is controversial. Most data come from studies with HCV-positive hemophiliacs and their female partners, and indicate extremely low risk. Most authorities do not routinely recommend the use of “safe sex” practices in HCV sero-discordant heterosexual couples. However, there have been several recent reports from the United States and Northern Europe of outbreaks of acute HCV infection in HIV-positive MSM. Per mucosal transmission of HCV-related to high-risk traumatic sexual and drug practices has been implicated as the infection route in these cases.

Although HCV infection is found worldwide, there is marked geographic variance in prevalence and incidence, and also between age groups within individual countries. In countries where IVDU is the major risk factor for HCV acquisition, such as North America, Northern Europe, and Australia, the highest prevalence rates are seen in adults aged 30–49, which would indicate an exposure in early adult life. In countries such as Italy and Japan, the majority of affected individuals are older, reflecting remote inadvertent transmission during medical interventions. In Egypt, prior mass parenteral therapy for schistosomiasis with contaminated needles is responsible for high rates of HCV prevalence in the general population.

Acute Hepatitis C—Clinical Features

Depending on the size of the inoculum, HCV RNA can be detected in serum from 6–7 days to 8 weeks after exposure, with the first biochemical evidence of infection. Approximately 80% of acutely infected individuals fail to clear the virus and develop chronic infection. Clinical factors favoring spontaneous resolution include age <40 years, female gender, and icteric presentation.

Following initial infection, HCV may become established despite the induction of a humoral immune response targeted against various epitopes of the HCV envelope glycoproteins. Strong and persistent proliferative responses of CD4⁺ T cells and the production of IFN- γ are associated with spontaneous viral clearance, whereas weak or transient responses are associated with progression to chronic infection. The role of CD8⁺ T cells in controlling acute HCV infection is less clear. It is known that IFN-treated individuals who have cleared HCV have decreased HCV-specific immune responses as compared with those achieving spontaneous clearance. There is some evidence that host genetic factors influence the outcome following HCV infection. Certain HLA class II alleles—HLA-DRB1*1101-DQB1*0301, DRB1*1104-DQB1*0301, and DRB1*0401-DQB1*0301 haplotypes—have been associated with a significantly increased likelihood of viral clearance, predominantly in Caucasian populations.

Chronic Hepatitis C—Clinical Features

Insulin resistance (IR) and the other components of the metabolic syndrome (obesity, hyperglycemia, hypertriglyceridemia, increased blood pressure, and low high-density lipoprotein cholesterol levels) and type II diabetes mellitus are more prevalent in individuals with chronic HCV than in healthy controls or patients with chronic HBV. The natural history of chronic HCV infection is variable, ranging from indolent to rapid progression to cirrhosis. Cohort studies have shown that 20% of individuals will progress to cirrhosis over 20 years.

Increased fibrosis progression is associated with male sex, longer duration of infection, acquisition of infection at age >40 years, excess alcohol consumption, immunosuppression, that is, from HIV coinfection or following organ transplantation, and coinfection with HBV, but it does not appear related to HCV genotype. Increased body mass index, visceral adiposity, and coexisting IR and hepatic steatosis may also increase the risk of fibrosis progression, and reduce response to IFN therapy, but these factors do not appear to have a negative impact on response rates with newer DAA regimens.

Diagnosis

Persistence of HCV RNA in the serum 6 months after initial infection indicates chronic HCV, although there are rare reports of spontaneous clearance up to 2 years after exposure.

Current commercially available tests for the detection of HCV antibody are based on either enzyme immunosorbent assays (EIA), which detect HCV-specific antibodies, or on recombinant immunoblot assays (RIBA). EIA's can diagnose more than 95% of chronic infections but can only detect 50%–70% of acute infections. RIBA assays identify antibodies that react with individual HCV antigens and are used as a supplemental test for confirmation of a positive EIA result.

Therapy of Chronic Hepatitis C

Unlike chronic HBV in which there is a “reservoir” of viral cccDNA in host cells with the potential for viral reactivation, there is no such reservoir in chronic HCV infection, and therefore HCV can potentially be eradicated with therapy. The previous “gold standard” of therapy for chronic HCV was the combination of pegylated IFN- α (Peg-IFN) injected subcutaneously once weekly, together with daily oral weight-based RBV, administered for 24 weeks to most patients with HCV genotype 2 or 3, and for 48 weeks to all other genotypes. The goal of therapy was the achievement of a sustained viral response or SVR, defined as undetectable serum HCV RNA levels (with sensitive PCR-based assays) 6 months after the completion of therapy. Mechanisms of action of IFN- α include the induction of an antiviral state that either protects cells from infection or attenuates the production of viral progeny in already infected cells, and, indirectly, the activation of the host adaptive immune response. RBV Both Peg-IFN and RBV have significant side effects, such as depression, fatigue, and cytopenias, and may be poorly tolerated. Efficacy of treatment is highly dependent on viral kinetics, HCV genotype, and ethnicity, with other factors such as gender, age, degree of liver fibrosis, and presence of HS and IR also playing a role. HCV genotype 1, African-American ethnicity, male gender, age >50 years and, advanced liver fibrosis with or without steatosis on liver biopsy are all negatively associated with response to Peg-IFN and RBV.

Owing to poor tolerability and low efficacy of combination Peg-IFN and RBV therapy, this regimen has been superseded by a novel approach to HCV therapy using “Direct Acting Anti-virals”: small-molecule inhibitors of the HCV encoded proteins that are vital to the replication of the virus (see HCV-virology). DAAs can be classified by their mechanism of action and therapeutic target into NS3/4 protease inhibitors, NS5A inhibitors and NS5B RNA polymerase inhibitors. These potent inhibitors of viral replication rapidly lower the serum HCV RNA levels to undetectable levels within a few weeks of starting therapy in the majority of patients. The probability of achieving SVR positively correlates with rapid reduction of plasma HCV RNA, as a prolonged period of aviremia while on therapy is beneficial because it allows a longer time for residual virus-infected cells to be eradicated. Data from phase 1 clinical trials showed that DAAs used as monotherapy quickly resulted in the virus developing mutations leading to drug resistance, (reminiscent of the experience seen in the development of antiretroviral drugs for HIV therapy). To prevent the emergence of resistance, DAAs therefore need to be given in combinations of two or more drugs with different viral targets, for example a NS5B

RNA polymerase inhibitor with a NS5A inhibitor. With DAA based regimens, SVR has been redefined as undetectable serum HCV RNA levels (with sensitive PCR-based assays) 3 months, rather than 6 months, after the completion of therapy, as clinical trials have shown that risk of viral relapse is negligible after this time point.

Over a decade ago the NS3 protease inhibitor BILN 2061 was the first DAA to be tested in humans, and although its development was halted at an early stage due to toxicity in animals, it provided “proof of concept” for this strategy. In 2011 the “first generation” NS3 protease inhibitors (PI) Telaprevir and Boceprevir were introduced, to be quickly superseded in 2013 by “second generation” drugs such as Sofosbuvir, Daclatasvir, and Simeprevir (by convention, the drug names of NS5B RNA polymerase inhibitors have the suffix *buvir*, NS5A inhibitors *asvir* and NS3/4 protease inhibitors *previr*). Sofosbuvir was the “first in class” NS5B RNA polymerase inhibitor, changing the landscape of HCV therapy owing to its unique properties, which included efficacy across all genotypes, once daily dosing, few side effects or drug–drug interactions, and a high genetic barrier against viral resistance.

Drug development has proceeded at pace, and in the United States and Europe many IFN free, all oral DAA drug combinations are now available, with minimal side effects and high rates of viral clearance with 8–12 weeks of therapy. Many are co formulated single tablet, once daily regimens, such as Sofosbuvir with Ledipasvir or Velpatasvir (second and third generation NS5A inhibitors respectively), Elbasvir with Grazoprevir (a third generation PI combined with a NS5A inhibitor), and the triple class combination of Paritaprevir/Ombitasvir and Dasabuvir. There are subtle differences between regimens with regards to drug–drug interactions and relative efficacy for different HCV genotypes, but overall these drugs are well tolerated and have SVR rates of over 95%. With the advent of more effective DAA regimens, the combination of Peg-IFN and RBV is no longer “standard of care” and has been removed from guidelines. RBV is still included in certain DAA regimens, depending on viral factors such as viral subtype (e.g., genotype 1a vs. 1b), “high” HCV RNA level, the presence of viral resistance associated mutations (RAS), and host factors such as cirrhosis. Current trials with the next generation of DAAs are ongoing, with the aim of reducing length of therapy down to 4 or 6 weeks, whilst maintaining SVR rates close to 100% irrespective of factors such as viral genotype, “high” HCV viral load, the presence of RAS, or cirrhosis.

Due to the overwhelming success of DAA therapy, it is postulated that HCV could be eradicated in the near future, using treatment as prevention and targeting populations in which HCV transmission is ongoing, such as IV drug users. Unfortunately due to the high cost of these regimens, the availability of these drugs in resource poor, but high prevalence countries is likely to be limited, although lower cost versions of certain DAAs have been made available through partnerships with generic manufacturers in these countries. The global eradication of HCV seems a tangible goal, but may still prove challenging.

Vaccines

Currently, no vaccine is available to protect against infection with HCV. During HCV replication, HCV sequences are continually evolving due to the error prone NS5B RNA dependant RNA polymerase, and the resulting viral diversity (quasi—species) creates obstacles for vaccine development with regards to the selection of target antigens, and the potential of escape from vaccine induced immune responses. Vaccine development has also been hampered by the lack of a suitable small animal model with which to assess the immunogenicity and protective efficacy of HCV candidate vaccines. Efficacy data has been obtained from chimpanzee models which have shown that it is possible to induce immune responses with vaccines that could inhibit viral replication, even if persistent infection was not prevented in all vaccinated animals. Prophylactic vaccines can be divided into those designed to induce T-cell responses, targeting HCV nonstructural proteins, and those designed to induce neutralizing antibodies targeting the envelope glycoproteins E1 and E2. New approaches, including peptide, recombinant protein DNA and vector vaccines have been evaluated in Phase 1/11 human clinical trials. A vaccine using recombinant E1 E2 proteins adjuvanted with MF59 has been tested in healthy volunteers and found to be safe, immunogenic, and to induce antibodies that neutralize HCV in vitro. Further development of this vaccine appears to be focusing on the induction of both neutralizing antibodies and T-cell responses by combining the recombinant E1 E2 protein with adenovirus vectors expressing the envelope glycoproteins of HCV. An immunocompetent, genetically humanized mouse model expressing the human orthologues of HCV has recently been developed that can support HCV entry but not full viral replication, and may aid future vaccine studies.

HDV

HDV, a defective RNA virus also referred to as Delta agent, infects nearly 20 million people worldwide, with a varying geographical distribution. It is only found in association with HBsAg—either as a coinfection in acute hepatitis B or as a “super infection” in an individual with chronic HBV infection.

Virology

First identified in 1977, HDV is deemed “defective” as it is unable to replicate by itself, requiring HBsAg as a protein “coat” for the HDV genome. HDV virions are 36–43 nm, roughly spherical, enveloped particles with no distinct nucleocapsid structure. The outer envelope contains lipid and all three forms of HBsAg (S, M, and L, but predominantly small). The genome of HDV (cloned and sequenced in 1986) consists of a compact (approximately 1.7 kb in length) circular single-stranded negative RNA molecule, which contains several sense and antisense ORFs, only one of which is functional and conserved. The RNA genome replicates via an RNA

intermediate, the antigenome, both of which can function as ribozymes to carry out self-cleavage and self-ligation reactions. A third RNA, complementary to the genome and found in the infected cell, is responsible for synthesis of the delta antigen. To date, there have been three genotypes and two subtypes of HDV have been characterized, but emerging data suggest that the genetic variability of the HDV genome is more complex than previously thought. Genotype 1 is mainly found in North America, Asia, Middle East, and Europe; genotype 2 in East Asia; and genotype 3 in South America. Genotype 2 is thought to cause less severe disease than the other two genotypes.

HDV genomic replication is not acutely cytopathic, and does not occur in cells other than hepatocytes; hence, the liver is the only organ affected. HBV is essential for the evolution of the hepatocellular necrosis and inflammation seen with HDV infection. Both humoral and cellular immune mechanisms are thought to be involved.

Epidemiology

Like HBV, HDV is transmitted by blood-borne and sexual routes, but in contrast perinatal transmission is rare. Infection with HDV has a global distribution, with two distinct epidemiologic patterns. First, high prevalence areas for HDV coincide with certain areas of high prevalence for chronic HBV infection, including the Mediterranean, Middle East, Central Africa, and the Amazon Basin in South America (Fig. 8). In these areas, viral transmission takes place predominantly by nonpercutaneous means, especially close personal contact. It is not known why HDV coinfection is not seen in other countries with a high prevalence of HBV, such as Southeast Asia and China. The second pattern is of parenteral transmission in subjects with multiple parenteral exposures, primarily injection drug users and hemophiliacs, as is seen in nonendemic areas such as Northern Europe and the United States. Worldwide, HDV infection is declining due to control of HBV. Even in Italy, an HDV-endemic area, public health measures introduced to control HBV infection there resulted in a significant reduction in the prevalence of HDV infection.

Clinical Features

The outcome of infection with HDV depends on whether HDV and HBV infect simultaneously (coinfection) or if HDV is acquired by an individual with chronic HBV (superinfection). Mortality from HDV infection is 10 times higher than for HBV alone.

In coinfection, both acute HBV and HDV hepatitis occur. Whether one or two bouts of clinical hepatitis are seen depends on the relative titers of HBV and HDV. The incubation period of acute HDV is between 3 and 7 weeks, with a preicteric phase lasting 3–7

Fig. 8 Geographic distribution of hepatitis D. Reproduced from Center for Disease Control and Prevention, USA.

days, during which time the classic symptoms of acute hepatitis are manifested (fatigue, lethargy, anorexia, and nausea), and ALT and AST become elevated. This phase is followed by jaundice, which can last for several weeks. The severity of the resulting illness is typically greater than with HBV monoinfection, with a higher incidence of fulminant hepatitis, and low risk of chronic infection (<5%). During the acute phase of HDV infection, synthesis of both HBsAg and HBV DNA is suppressed until HDV is cleared.

Hepatitis D superinfection is frequently associated with severe acute hepatitis with progression to chronic HDV in up to 80% of cases. Fulminant hepatitis also occurs. Superinfection can transform inactive or mild chronic hepatitis B into severe, progressive chronic hepatitis, and result in faster progression to cirrhosis than seen with chronic HBV alone. Up to 70% of patients with chronic HDV will develop cirrhosis.

Diagnosis

Anti-HD IgM, HDV RNA, and HDAg are the most sensitive markers for the diagnosis of acute HDV, although anti-HDIgG is the only test commercially available. Detection of serum HDV RNA by PCR is the “gold standard” for confirming infection.

In acute HBV–HDV coinfection, HBsAg precedes the appearance of HDAg and HDV RNA. Anti-HDIgM develops late in the acute phase, and is accompanied by the disappearance of HDAg. In about 15% of patients the only evidence of HDV infection may be the detection of either IgM anti-HDV alone during the early acute period of illness or IgG anti-HDV alone during convalescence. Both IgM and IgG anti-HD antibodies decline after recovery to subdetectable levels within months to years, and it can sometimes be difficult to demonstrate past HDV infection as there is no serologic marker that persists to indicate that the patient was ever infected with HDV. These immune responses are thought to be protective, as second cases of HDV have not been reported.

With HBV–HDV superinfection, HBsAg titers decline with the appearance of HDAg in the serum. HDV RNA levels reach a peak between 2 and 5 weeks after exposure, declining over a period of 1–2 weeks. High titers of IgM and IgG anti-HD are detectable in the acute phase, and can persist for months or even indefinitely. Most superinfections result in chronic HDV, demonstrated by the persistence of HDV RNA, and high levels of IgM and IgG anti-HD. HDV viremia is associated with active liver disease.

Therapy

High-dose IFN- α (up to 9 million units three times weekly for 48 weeks) has been evaluated in individuals with chronic HDV, although standard IFN has now been superseded by Peg-IFN. Interferon therapy does not achieve viral eradication in the majority of those treated, although improvement in biochemical and histological parameters has been observed. Prolonging therapy for greater than 12 months may be of benefit in certain patients if eradication of HBV sAg is used as an endpoint. The development of specific antiviral therapy against chronic HDV has been impeded due to the lack of specific enzymatic targets in the virus. HDV virion assembly requires prenyl lipid modification (or prenylation) of its nucleocapsid—like protein large HDV antigen. Prenylation inhibitors are currently in clinical development and other viral processes which are potential targets for inhibition include acetylation, phosphorylation and methylation. Lonafarnib (a farnesyl transferase inhibitor) is being evaluated in combination with Peg-IFN in clinical trials. Treatment of the associated HBV infection with oral antiviral drugs does not alter the course of HDV infection.

Vaccines

No vaccine is available specifically for delta virus; however, as this virus is only acquired in association with HBV, vaccination against HBV will also prevent against the transmission of HDV. HBIG will not protect individuals with chronic HBV from infection with HDV.

HEV

HEV is an enterically transmitted RNA virus responsible for outbreaks of hepatitis in developing countries and sporadic cases of acute hepatitis in endemic areas such as Southeast and Central Asia (Fig. 9). Locally acquired hepatitis E in individuals who have not traveled to endemic areas is, however, becoming an emerging problem in European countries.

Virology

Although recognized as a clinical entity in the 1980s, the virus responsible for acute enterically transmitted NANB hepatitis was not identified until 1983. HEV has recently been classified in the genus *Hepevirus* of the family *Hepeviridae*.

Cloned in 1990, the HEV genome is a nonenveloped, single-stranded, positive-sense RNA molecule 7.2 kb in length, with three ORFs. ORF 1 codes for viral enzymes methyltransferase, proteases, helicase, and replicase; ORF 2 codes for the major HEV capsid protein, the function of the protein coded for by ORF 3 has not yet been well characterized, although it appears to be involved in virus–host interactions. Four major genotypes have been identified, geographically distinct, but all share at least one major serologically cross-reactive epitope despite substantial genomic variability, which is an important observation that may facilitate the development of a protective vaccine.

Fig. 9 Geographic distribution of hepatitis E. Reproduced from Expert Reviews in Molecular Medicine, 2003, Cambridge University Press.

Viral replication, transcription, virus–host interactions, and pathogenesis of HEV are poorly understood due to the lack of a cell culture system and a practical animal model for HEV. Subgenomic expression strategies have been used to fractionally characterize HEV-encoded proteins. However, in common with other hepatitis viruses, the mechanism of liver injury is probably immunological, as the onset of ALT elevation and histopathological findings of acute hepatitis correspond with the appearance of antibodies to HEV and decreasing levels of HEV antigen in hepatocytes.

Epidemiology

Outbreaks of acute HEV infection affecting several thousand people have been reported from Asia, the Middle East, Northern and Western parts of Africa, and Central America. HEV is transmitted through the fecal–oral route and most epidemics have been associated with contaminated drinking water. Although like HAV, HEV is detectable in the stools of infected individuals, person-to-person transmission is less commonly observed, and sexual transmission is debatable. Parenteral transmission of HEV is possible, with reports of individuals infected from receiving contaminated blood products. Risk of infection is linked to the amount of virus in the donor's blood, and the volume of plasma transfused. Materno-fetal transmission is possible, with recent data indicating maternal infection is associated with increased risk of preterm delivery, miscarriage, stillbirth or neonatal death. In contrast with perinatally transmitted HBV, there have not been reports of chronic HEV infection in children born to mothers with HEV.

HEV has four genotypes, with differences in epidemiology being observed between genotypes; genotype 1 is predominant in developing countries, causing community level outbreaks, whilst genotype 3 is generally responsible for isolated infections in developed nations. The spectrum and magnitude of disease caused by HEV genotype 3 is still being characterized.

HEV is a common cause of sporadic hepatitis in endemic areas, accounting for almost 50%–70% of acute hepatitis cases in India. In industrialized nations, acute HEV infections are infrequent, accounting for <1% of cases of acute viral hepatitis, and are usually associated with a history of travel to an endemic area. However, there have been an increasing number of reports of nontravel-associated HEV from Europe, United States, and Japan, and in these cases it has been postulated that HEV may have been acquired from a viral reservoir in swine or possibly rodents. In support of this theory, high seroprevalence of anti-HEV has been reported in pig veterinarians, and farm workers in contact with pigs. In Japan, cases of acute infection associated with the consumption of inadequately cooked pig liver have been reported. HEV may therefore be viewed as a new emerging pathogen with zoonotic potential.

There is evidence that subclinical infection may be common in endemic areas; one study reports HEV seroprevalence rates of 30%–50% in healthy subjects. Another study from Southeast Asia followed up a cohort of healthy individuals over an 18-month period and found that 66% of those who seroconverted to anti-HEV had no history of jaundice, suggesting that such “subclinical” cases may act as reservoirs for infection in endemic populations and also as a source for cases of sporadic acute HEV.

Clinical Features

As for hepatitis A, the attack rate is highest for young adults aged between 15 and 40. Work with susceptible primate models and infected individuals reveals that the incubation period is approximately 21 days, with the expression of HEV antigen in the serum and stool occurring 7 days before the onset of symptoms, and persisting for approximately 2 weeks. ALT and AST begin to rise a few days before the onset of symptoms, but generally return to normal within 1–2 months after the peak severity of the disease has passed. Anti-HEV (IgM) appears shortly after the onset of clinical illness and persists only for a few months. IgG anti-HEV appears a few days after IgM and persists for up to 3 years, and may afford protection against reinfection.

Clinical features are similar to other acute viral hepatitis. Acute HEV infection is often mild and self-limiting in immunocompetent individuals, but can cause fulminant liver disease in persons with underlying cirrhosis and pregnant women, particularly during the third trimester of pregnancy when mortality rates of up to 25% have been reported. Surveillance data from rural Bangladesh indicates that acute hepatitis, most likely due to HEV, is responsible for approximately 10% of pregnancy associated deaths. Disease severity may correlate with HEV genotype, genotype 3 appears to be associated with milder disease. In Japan where 3 and 4 are the most prevalent HEV genotypes, two studies found that patients with genotype 4 experienced higher peak ALT levels and longer hospital stays as compared with patients with genotype 3. Chronic infection with HEV genotypes 3 and 4 has been described in the setting of solid organ transplantation and potent immunosuppression, such as used in stem cell transplants. Chronic HEV can cause significant liver disease. As transmission of the virus via contaminated blood is possible, several countries now screen all donated blood for HEV, whilst others, including the United Kingdom, only screen blood products for recipients most at risk of developing chronic infection (solid organ and stem cell transplant patients, neonates and infants under the age of 12 months).

Acute and chronic HEV infection may be associated with a number of acute neurological syndromes, including Guillain Barre syndrome (acute inflammatory demyelinating polyradiculopathy), neuralgic amyotrophy, meningo encephalitis, and transverse myelitis. HEV RNA has been demonstrated in the serum and cerebrospinal fluid in some affected individuals, implying a direct effect of the virus, but causality is not fully elucidated. It is not clear if damage to the central nervous system is mediated by an abnormal immune response triggered by the virus, or secondary to local viral replication. In the majority of these cases jaundice is not present, and there is only mild derangement of liver transaminases, making diagnosis difficult.

Diagnosis

Infection with HEV can be confirmed by the detection of IgM and IgG anti-HEV antibodies or the presence of HEV RNA in the serum detected by RT-PCR, HEV RNA can also be detected in stool. IgM anti-HEV antibodies can be detected during the first few months after HEV infection whereas IgG anti-HEV antibodies represent either recent or previous infection. Presence of HEV RNA in serum indicates current infection, either acute or chronic. Although commercial antibody assays are available, they can vary markedly in their sensitivity and specificity. Improved validation of existing assays, and the development of new assays with better performance characteristics is required.

Treatment

Some patients with chronic HEV may respond to a reduction in immunosuppression. If this approach is unsuccessful, antiviral therapy can be considered. Peg-IFN and RBV have previously been evaluated, but the use of Peg-IFN may lead to graft rejection in solid organ recipients and is not recommended in this setting. Although data is limited, RBV monotherapy for at least 3 months is the preferred option. In one retrospective multicentre case series of 59 patients treated with RBV monotherapy for a median duration of 3 months (range 1–18 months), a viral clearance rate of 78% was achieved.

Vaccines

There is currently no globally available licensed vaccine against HEV. In 2007, Shrestha and colleagues evaluated a recombinant HEV vaccine in (mostly male) volunteers in the Nepalese Army; the protective efficacy against clinically overt HEV infection was 95.5% in subjects receiving all three vaccine doses and 85.7% after two doses. Although the vaccine was efficacious and well tolerated, it was not developed commercially. In 2005, researchers in China began working on a new recombinant HEV vaccine. Results from a randomized clinical trial with over 100,000 participants indicated the efficacy of the vaccine was greater than 99% in those who received the full three dose series. The vaccine was subsequently approved and licensed by Chinese authorities in 2012, but it is not approved outside China.

“New” Hepatitis Viruses

Several recently discovered viruses, namely torque teno virus (TTV), SENV, and hepatitis G, although potentially hepatotropic, have yet to be conclusively shown to be pathogenic to the liver.

In 1994, an agent (initially named hepatitis F virus) was isolated from a stool sample and found to be transmissible in primates. Subsequent researchers have not been able to confirm the existence of this agent, and there is currently no confirmed HFV.

TTV

TTV, family Circoviridae, genus *Anellovirus*, has a single-stranded circular DNA genome. Related viruses are also found in primates, chickens, pigs, cows, sheep, and dogs. This virus was first identified in 2001 in a patient presenting with non-A–E acute recurrent hepatitis with no history of drug or alcohol abuse and negative markers of viral or autoimmune disease. Transmitted parenterally and probably also enterically, the TTV family of viruses is present in over 90% of adults worldwide. Human pathogenicity, particularly regarding the liver, has yet to be clearly established.

SEN Virus

Named after the initials of the patient with HIV from which it was first isolated, SEN virus (SENV) is a novel circular single-stranded DNA virus distantly related to TTV and also classified within the family Circoviridae, which has been associated in some studies with post-transfusion hepatitis. Variants designated A–H have been identified, which have differing geographical prevalence, for example, SENV-D is highly prevalent in Japan. Although it has been found more frequently in individuals with liver disease than the normal population there is no firm evidence that infection causes hepatitis or worsens the course of liver disease.

HGV

In 1995 and 1996 several new flaviviruses, GB-A, GB-B, and GB-C, related to but distinct from HCV, were identified. GB-A and GB-B infect tamarin monkeys but GB-C can infect humans and has been implicated in some cases of acute and chronic hepatitis. Another group identified a virus which they termed HGV; based on genomic sequence comparisons, HGV and GB-C can be considered the same virus. Another virus in this family, GBV-D, infects bats. GB viruses have recently been reclassified, due to similarities in genome organization and pathogenic features, into the tentative genus Pegivirus within the family Flaviviridae.

HGV is a positive-stranded RNA virus, which has at least four major genotypes. It is thought to be lymphotropic, replicating predominantly in the spleen and bone marrow. Molecular epidemiological studies have demonstrated that about 1%–1.4% of the healthy population in developed countries are chronically infected with HGV. Parenteral is the most frequent mode of infection, and HGV has been implicated in a small number of cases of posttransfusion hepatitis. There is also a higher prevalence of HGV in drug users and patients on hemodialysis. Whether HGV is a significant cause of human hepatitis is still unconfirmed. Although relatively common, infection with HGV may cause a mild acute hepatitis but does not seem to cause clinically significant chronic liver disease. In one US study evaluating causes of acute viral hepatitis, HGV RNA was detected in 9% of patients with acute non-A–E hepatitis, 20% of those with HCV, 25% of those with HAV, and 32% of those with HBV. Another study examined serum samples from blood donors, transfusion recipients and controls. Prevalence of HGV in the nontransfused individuals ($n = 657$) was 1.4%. There were 35 HGV infections among the 357 transfusion recipients, with only three having HGV as the only agent detected. All these subjects had a mild hepatitis and did not develop clinically apparent chronic hepatitis (although liver biopsy was not performed).

A French study retrospectively examined 228 subjects with chronic HCV for HGV coinfection; 21% of the cohort and 32% of the subset who were IVDUs were coinfecting. Another French study found that 57.5% of a cohort of 61 hemodialysis patients tested positive for HGV RNA; however, only four of these subjects had viremia associated with elevated serum ALT.

Several studies in HCV coinfecting individuals, although with small numbers of subjects, have established that severity of liver disease, serum HCV RNA levels, and response to IFN therapy are not influenced by HGV coinfection. HGV RNA levels were observed to decrease with IFN therapy, but most subjects became detectable again once IFN was discontinued.

Future Prospects

Prospects for lessening both mortality and the socioeconomic burden resulting from viral hepatitis are optimistic, because safe and effective vaccines are currently commercially available for HAV and HBV, and a vaccine for HEV is available, albeit currently only in China. Improvements in sanitation and dissemination of simple public health information will lessen the transmission of HAV and HEV in endemic areas. Pretransfusion screening of blood and blood products for infectious agents is now routine in the majority of developed countries, thus lessening the iatrogenic transmission of HBV, HDV, and HCV. In Asia, where vertical transmission of HBV constitutes the major route of infection, increasing maternal HBV screening, and use of both active (administration of HBV vaccine) and passive (administration of hyperimmune globulin) immunoprophylaxis for infants at high-risk will prevent most neonatal infections, leading to a decreased incidence of chronic HBV-related complications (such as HCC) in these populations over time. Owing to particular viral characteristics, development of a vaccine for HCV remains a scientific challenge with no current indication of when such a vaccine might be available, however prospects are improving due to advances in vaccine technology and the understanding of HCV immunity and replication, and the availability of novel tools to test antibody responses. Fortunately, the incidence of HCV, at least in the Western world, is declining because of routine screening of blood and blood products before transfusion, and the implementation of risk minimization strategies, for example, needle exchange programs, in populations such as IVDUs. In chronic HBV, although long-term viral suppression can be maintained in the majority of patients using currently available oral therapies, achieving viral eradication is problematic. There are a large number of drugs in early clinical development, ranging from immunostimulatory agents to new antiviral targets and HBV entry inhibitors, which aim to bring about eradication of viral reservoirs with finite therapy. The treatment of chronic HCV has evolved dramatically, firstly with the introduction of novel protease inhibitor therapies in 2011, and the arrival in 2013–14 of highly efficacious and well tolerated “second generation” direct acting antivirals. Such is the potency of these agents that there is the potential to cure the majority of individuals with HCV, providing that access to these therapies globally is not impeded by the high costs of these regimens.

Many cases of acute hepatitis occur without any identification of a causative agent, viral or otherwise, which would imply that there are additional pathogenic hepatotropic agents. The search for these agents will provide a continuing diagnostic and therapeutic challenge.

Glossary

Antiviral drugs A class of medication used specifically for treating viral infections. As with antibiotics for bacterial infections, specific antivirals are used for specific viruses.

Immunocompetent An individual with a normal immune system; the individual is capable of developing an immune response to an infection.

Immunocompromised An individual whose immune system is compromised in some way, the individual lacks the ability to mount a normal immune response to an infection and is often unable to resist or fight off infection.

Latency A quiescent period of infection when most or all of the viral lytic genes are silenced, and the virus is not making progeny virus.

Lytic A type of infection in which viral lytic genes are switched on and the virus is actively undergoing replication and making progeny virions. This is also referred to as a productive infection.

Seropositive A situation where an individual has antibodies against a certain pathogen in their blood, being seropositive indicates that the individual was previously exposed to that pathogen.

Vaccine A preparation that contains an antigen, consisting of an organism or a part of an organism, that is used to confer immunity against the disease that the organism causes. Vaccines can be natural, synthetic or derived from recombinant DNA technology.

Abbreviation

ACV	Acyclovir
BL	Burkitt's lymphoma
CAEBV	Chronic active EMV
CD21	Complement receptor 2
CD8 ⁺	Cluster of differentiation 8
E genes	Early genes
EBNA	EBV-coded nuclear antigens
EBV	Epstein-Barr virus
ES	Exanthem subitum
HCF	Host cell factor
HCMV	Human cytomegalovirus
HHV	Human herpesvirus
HHV-4	Human herpesvirus 4
HHV-6	Human herpesvirus 6
HHV-8	Human herpesvirus 8
HPC	Hematopoietic progenitor cells
HSE	Herpes simplex encephalitis
HSK	Herpetic stromal keratitis
HSV	Herpes simplex virus
IE genes	Immediate early genes
IFN- γ	Interferon- γ
IM	Infectious mononucleosis
KS	Kaposi's sarcoma
KSHV	Kaposi's sarcoma-associated herpesvirus
L genes	Late genes
LATs	Latency-associated transcripts
LCV	<i>Lymphocryptovirus</i>
LMPs	Latent membrane proteins

[☆]Change History: September 2014. AL van Lint and DM Knipe updated the text and further readings to this entire article.

This article is an update of A.L. van Lint, D.M. Knipe, Herpesviruses, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 376–390.

MCMV	Models with murine CMV
MHC	Major histocompatibility complex
NHANES	National Health and Nutrition Examination Survey
NK cells	Natural killer cells
NPC	Nuclear pore complexes
Oct-1	Octamer binding protein 1
PEL	Primary effusion lymphoma
PHN	Post-herpetic neuralgia
PTLD	Posttransplant lymphoproliferative disease
RDV	<i>Rhadinovirus</i>
TK	Thymidine kinase
VAHS	Virus-associated hemophagocytic syndrome
VHS	Virion host shutoff
VP16	Viral protein number 16
VZV	Varicella-zoster virus
XLP	X-linked lymphoproliferative

Defining Statement

The family *Herpesviridae* includes over 100 different species of DNA viruses, eight of which are currently known to infect humans. These viruses are discussed with relation to the diseases they cause, their ability to establish latent infections, their biology, replication and pathogenesis, and the treatment options available for each.

Family *Herpesviridae*

The family *Herpesviridae* is a family of large DNA viruses containing over 100 different virus species that infect hosts ranging from humans to birds to reptiles. Classification of a virus as a member of the family *Herpesviridae* is based on a shared virion structure: a linear, double-stranded DNA genome is contained within a central core, surrounded by an icosahedral capsid. This capsid is in turn surrounded first by an amorphous protein layer, known as the tegument, and then by an envelope containing viral glycoprotein spikes (Figure 1). Herpesviruses also share four significant biological properties:

1. They encode a large number of enzymes involved in nucleic acid metabolism, DNA synthesis, and processing of proteins.
2. The synthesis of viral DNAs and capsid assembly occurs in the nucleus of the infected cell. During infection, virus-specific compartments are assembled within the nucleus of the infected cell, commonly referred to as replication compartments (Figure 2). It is within these compartments that viral DNA replication, late viral gene expression, and encapsidation of progeny viral genomes occur. These compartments lead to the formation of basophilic nuclear inclusion bodies, which are diagnostic of herpes virus infection.
3. Production of infectious progeny virus is generally accompanied by the destruction of the infected cell.
4. The viruses are able to establish a latent infection in their natural hosts.

There are currently eight herpesviruses that are known to infect humans: herpes simplex virus (HSV)-1 and HSV-2, human cytomegalovirus (HCMV), varicella-zoster virus (VZV), Epstein-Barr virus (EBV), Kaposi's sarcoma-associated herpesvirus (KSHV) and human herpesvirus (HHV)-6 and HHV-7. These viruses, along with the majority of herpesviruses that infect other

mammals and birds, have been divided into three subfamilies, alpha, beta, and gamma, based on the biological properties of the viruses. HSV-1, HSV-2, and VZV are members of the *Alphaherpesvirinae* subfamily, EBV and KSHV are both members of the *Gammapherpesvirinae* subfamily, while the remaining viruses, HCMV and HHV-6A, HHV-6B, and HHV-7 are all members of the *Betaherpesvirinae* subfamily. Despite the many similarities in structure and biological properties shared by herpesviruses, it is not surprising that in a group of this size there are also many differences. Host range, length of replicative cycle, cell type in which latency is established, and clinical manifestations of disease all vary among the different members of the family.

The *Alphaherpesvirinae* Subfamily

Members of the *Alphaherpesvirinae* subfamily are characterized by a variable host range, short reproductive cycles, the ability to spread rapidly in culture and efficiently destroy infected cells, and the capacity to establish latent infections primarily, although not solely, in sensory ganglia. The members of the *Alphaherpesvirinae* subfamily that infect humans are HSV-1 and HSV-2, and VZV.

Herpes Simplex Virus

Disease

The two HSV species, HSV-1 and HSV-2, are capable of causing a variety of diseases within an infected host. The most common of which are orolabial lesions, commonly referred to as cold sores or fever blisters and most often caused by HSV-1, and genital herpes which is most often caused by HSV-2. The viruses are extremely widespread throughout the world's population. The US National Health and Nutrition Examination Survey (NHANES) conducted between 2005 and 2010 has put seroprevalence rates in the United States at 54% for HSV-1 and 16% for HSV-2. Seroprevalence rates in Europe tend to be slightly higher for HSV-1 and slightly lower for HSV-2 when compared to the United States, although there are large intercountry differences. In developing Asian countries, the seroprevalence of HSV-1 and HSV-2 appear to match those seen in Europe and the United States. However, in Africa and Central and Southern America, the picture is quite different. In these regions, HSV-1 is becoming an almost ubiquitous pathogen with greater than 90% of the population seropositive by their fourth decade of life. HSV-2 seroprevalence rates range from 30% to 80% in women and 10–50% in men in sub-Saharan Africa, and between 20% and 40% in women in Central and South America. Universally, HSV-2 seropositivity is higher in women than in men. Changes in sexual practices also mean that HSV-1 is becoming a more common cause of genital infection than it once was.

In an immunocompetent host, primary infections with HSV can be asymptomatic, with an individual only realizing that they have been infected when a recurrent infection occurs at a later point. However in some cases, primary infections can be symptomatic, and in these instances disease is usually more severe than that seen with recurrent infection. During symptomatic primary HSV infection, individuals can present with fever, malaise, and large quantities of painful vesicular lesions at and around the site of infection, lasting for a period of up to 3 weeks. Recurrent infections, at either the orofacial or genital site, generally involve a much smaller number of vesicular lesions that persist for 7–10 days.

Along with the common mucosal herpetic lesions associated with orofacial and genital infections, HSV is also associated with a number of more severe complications. In immunocompetent individuals, the most serious complications are herpetic stromal keratitis (HSK) and herpes simplex encephalitis (HSE). Ocular infection with HSV can lead to HSK, the leading cause of infectious corneal blindness. Initially, recurrent infections within the cornea can produce ulcers that result in pain, light sensitivity, and blurred vision. Repeated episodes of recurrent disease can lead to involvement of the underlying stroma, resulting in HSK, which can eventually lead to blindness due to corneal scarring and vascularization. HSE, while extremely rare, has a high risk of mortality if left untreated (>70%). It is usually caused by HSV-1 and results in inflammation and swelling of the brain tissue, with patients

presenting with weakness, visual disturbances, and seizures. Although antiviral drugs can be used to decrease mortality, almost 50% of patients fail to regain complete normal function.

As is common with herpes viruses, individuals with compromised or absent immune responses are at high risk of HSV complications. Patients with atopic dermatitis, where the immune response in the skin is skewed toward a Th2 response, can develop a disseminated HSV infection throughout the skin known as eczema herpeticum. Evidence from HIV-positive patients and people undergoing immunosuppressive therapy has demonstrated the increased severity of HSV infection in such populations, with these patients also more prone to chronic or atypical infections. Finally, HSV infection in neonates is associated with increased mortality and morbidity. Infection in this setting usually results from transmission from mother to child during delivery and is estimated to occur at a rate of one in every 3–5000 deliveries. Localized infections of the skin, eyes, and mouth are rarely fatal. However, children with disseminated infections or those involving the central nervous system are at high risk of mortality or ongoing neurological impairment. Prompt antiviral treatment has been able to reduce mortality rates; however, neurological sequelae remain high in children who recover from either disseminated HSV or HSV encephalitis.

Virus and Biology

The genome of HSV-1 is approximately 152 kbp in length, while that of HSV-2 is approximately 154 kbp. The two viruses have approximately 50% nucleotide sequence identity and encode protein products with high levels of amino acid sequence identity. Both viruses have the same genome structure of a unique long and unique short region flanked by inverted repeats and share the common herpesvirus virion structure described previously. The high level of shared protein sequence results in antigenic cross-reactivity between the two viruses but despite this they have different neutralization patterns and tend to produce different clinical symptoms.

One biological property, common to both HSV-1 and HSV-2, that influences the ability of these viruses to cause disease in humans is neurovirulence. The ability of the virus to invade and replicate within the host nervous system primarily enables the virus to establish a latent reservoir of virus within this site, from which reactivation and subsequent transmission can occur. However, it also provides a situation whereby the virus can produce severe disease within the host, such as is seen in cases of HSV encephalitis.

Replication

In permissive cells, the process of HSV viral replication takes 18–20 h (Figure 3). The initial step in this process is the attachment to and entry of the virus into the target cell, a process that involves five viral glycoproteins – gB, gC, gD, gH, and gL. The initial attachment is mediated by contact between glycoprotein C (gC) and/or gB with heparan sulfate on the surface of the cell. Viral

Figure 3 Replication cycle of herpes simplex virus (HSV). The virus binds to the cell surface and the capsid and tegument are released into the cytoplasm following fusion of the viral envelope with the plasma membrane. The capsid is transported to the nuclear pore, and the viral DNA is released into the nucleus and becomes circularized. The host RNA polymerase II transcribes the immediate early (IE) genes, and the mRNAs are transported into the cytoplasm where translation occurs. The IE proteins activate transcription of the early (E) genes that are involved in viral DNA replication. Viral DNA replication occurs within replication compartments and stimulates transcription of the late (L) genes. The L proteins are involved in assembling the capsids within the nucleus. Progeny viruses exit from the cell by one of three potential mechanisms described in the text.

attachment is closely followed by interaction between gD and one of the several cell surface receptors that facilitate entry into the cell; three different classes of receptors have been identified for gD. Viral entry can occur via two pathways, the well-characterized method of direct penetration of the cellular membrane via fusion with the viral envelope and the less well-characterized method of endocytosis. This second method of entry has to date only been demonstrated using *in vitro* systems with several different cell lines. Hence, the importance of endocytosis in a natural infection remains to be determined. The kinetics of both modes of viral entry appears to be similar, with the transition from attachment to penetration occurring within minutes.

Following entry into the cell, the de-enveloped viral capsid is transported through the cytosol to the nuclear pore complexes (NPC) where the viral DNA is released into the nucleus and takes on a circularized form. Movement of the capsid through the cytosol is rapid, reaching the nucleus within approximately 1 h. This transport is mediated by microtubules. Once the viral DNA has entered the nucleus, the host RNA polymerase II is then used to transcribe the viral genome in a sequential fashion, resulting in the expression of over 80 viral proteins. The viral proteins are preferentially translated within the infected cell, in part due to the action of the viral protein VHS (virion host shutoff). This tegument protein remains in the cytoplasm as the viral capsid is transported to the nucleus. It induces destabilization of host mRNA and causes a rapid cessation of host protein synthesis, resulting in the loss of the cellular mRNA pool and the preferential translation of viral mRNAs. The sequential pattern of viral gene expression results in the HSV genes being divided into three categories, loosely based on the timing of their expression in infected cells. The categories are the immediate early (IE) or α genes, the early or β genes, and the late (L) or γ genes.

IE Genes

The IE genes are expressed within 2–4 h of infection and include six different viral proteins. These genes can be expressed in the absence of *de novo* viral protein synthesis, using the viral tegument protein VP16 (viral protein number 16) as a transactivator. VP16 is transported to the nucleus with the cellular host cell factor (HCF) protein. Once within the nucleus, the VP16–HCF complex binds to a second cellular factor, Oct-1 (octamer binding protein 1) and forms a stable transcription regulatory complex called the VP16-induced complex. This complex recruits transcription factors, histone-modifying enzymes and chromatin-remodeling complexes to stimulate expression of the IE genes.

The IE genes ensure the orderly expression of subsequent viral genes and the evasion of the cellular responses to the infection. To do this, many of the IE genes perform multiple functions, and a variety of forms of posttranslational processing is employed to enable these proteins to fulfil the roles required. In brief, ICP4 is required for the expression of all early (E) and L genes; ICP0 acts as a nonspecific or ‘promiscuous’ transactivator, capable of stimulating the transcription of α , β and γ genes; ICP27 is required for the transcription of the L viral genes and some E genes; ICP47 is involved in immune evasion; and ICP22 and U_S1.5 are thought to be involved in promoting the expression of some L genes.

E Genes

The E genes are maximally expressed between approximately 5–7 h after infection. The E proteins include those that make up the viral DNA replication machinery. Thus, the expression of the E genes signals the initiation of viral DNA replication. However, the expression of certain E genes is also involved in downregulating IE gene expression, in particular, ICP8 has been shown to downregulate expression of the IE gene ICP4.

L Genes

The L genes are the final group of viral genes to be expressed within the infected cell. Some L genes, such as gB and gD, are actually expressed early in the infected cell, and their expression simply increases with the onset of viral DNA replication. Alternatively, other L genes, including gC and U_S11, are only expressed following viral DNA replication. Many of the L genes encode viral structural proteins, and their expression enables the production of progeny virion particles.

Viral Egress from Infected Cells

Following the expression of the L genes, viral capsids are assembled within the nucleus. These capsids, predominantly made up of four viral proteins, are then filled with viral DNA, a process that utilizes viral proteins. It is generally accepted that the nucleocapsids then bud through the inner nuclear membrane and upon doing so acquire an envelope. However, the subsequent events that lead to the egress of the newly formed virus particle from the infected cell are not yet fully understood. Three competing theories exist, each with varying amounts of supporting evidence. (1) The enveloped virus fuses with the outer nuclear membrane, leaving the de-enveloped nucleocapsid to bud into the Golgi apparatus, regaining an envelope, and then to travel to the surface via vesicular movement. In this model, the tegument could be acquired in the nucleus or the cytoplasm, with work supporting this model demonstrating that the majority of virions gain their tegument and envelope in the cytoplasm. (2) The enveloped nucleocapsid buds through the inner nuclear membrane and is transported to the surface by vesicular movement through the Golgi apparatus;

thus, in this model, the tegument would be acquired in the nucleus. (3) Capsids exit the nucleus via nuclear pores and then bud through Golgi membranes.

Release of virus from an infected cell results in the shedding of newly formed virions, enabling the virus to spread to susceptible individuals. However, within the body, the virus can also spread directly from cell to cell. This process involves the viral glycoproteins gE and gI, which form a heterodimer, and is facilitated by cell contact. In general, cells infected with replicating HSV do not survive the infection, due to the cytopathic effects of viral infection.

Latent Infection

HSV persists for the life of the host by establishing a latent infection in sensory neurons. During a primary infection, virus enters the sensory nerve endings in the epithelium and travels to the neuronal cell body. Animal models have suggested that within the neuronal cell body viral replication can occur initially. However, within several days, no replicating virus can be detected. Concurrent with the short-lived lytic infection within the ganglia, the virus also establishes latency and, following clearance of the replicating virus, latent virus persists. Evidence from animal models and human studies has indicated that the latent HSV genome most likely exists as an extrachromosomal circular episome, with human studies suggesting a latent viral burden of between 1 and 10 viral copies per neuron, remembering that not all neurons within a ganglion will harbor latent virus. Viral replication within the nerves or even at the primary site of infection is not required for the establishment of latency. However, lack of viral replication appears to reduce the quantity of latent virus within a latently infected ganglion through a reduction in the number of latently infected cells.

The traditional view of latency is that lytic viral gene expression is shut down and only the latency-associated transcripts (LATs) are produced. The primary LAT is an 8.5 kb transcript that is cleaved to produce the 2.0 and 1.5 kb major LATs, referred to as such based on their abundance, and several microRNAs. LATs may play a role in silencing lytic genes, preventing cell death, or exerting other effects during latent infection.

As mentioned previously, latent virus can reactivate periodically. It is thought that only a small percentage of latently infected neurons will reactivate at any given time. Following reactivation within the ganglion, either virions or viral components such as the nucleocapsid and the glycoproteins travel down the neuroseparately via anterograde axonal flow and are assembled into virus particles prior to virus emergence into the periphery. Within the periphery, reactivated virus can result in either asymptomatic shedding or a clinical recurrent lesion. Although the mechanisms are not fully understood, a number of stimuli are known to induce reactivation including nerve damage, stress, ultraviolet (UV) light, menstruation, and hormonal imbalances. The fate of virus-infected neurons continues to be contentious, with some believing that neurons can survive a lytic HSV-1 infection and others arguing that they cannot.

Pathogenesis

Transmission of HSV requires close, personal contact between the susceptible individual and an individual secreting the virus, enabling the virus to come into contact with either mucosal surfaces or abraded skin. As previously mentioned, HSV-1 is generally the cause of orofacial infections while HSV-2 is usually transmitted via genital contact, and thus causes genital infections, although it should be noted that both viruses are capable of infecting either sites. At each site, the virus replicates in the epithelium and infects the innervating sensory nerve endings. Virus travels along the neuronal axon to the innervating sensory ganglion, the trigeminal ganglion in orofacial infections, and the sacral ganglia in genital infections. Within the sensory ganglion, HSV establishes a lifelong latent infection in which viral gene expression is silent except for transcription of the LAT.

A major factor in the pathogenesis of HSV is the ability of the virus to reactivate from latency. Although we do not yet fully understand the mechanisms through which this occurs, it has been demonstrated that the frequency of reactivation correlates with the severity of the primary infection. When reactivation occurs, progeny virions are produced within the ganglion and travel back down the neuronal axon to be released into the epithelium at or near the site of initial infection. Such reactivation events, which can be either symptomatic or asymptomatic, provide the virus with the opportunity to spread to other susceptible individuals. Interestingly, HSV-1 is more likely to reactivate within a trigeminal ganglion than a sacral ganglion, while the opposite is true for HSV-2. In this way, the tissue tropism of each virus appears to be coupled with a site-specific frequency of reactivation.

Drugs and Vaccines

A number of nucleoside analogues have been used effectively to treat herpes infections, including acyclovir (ACV), famciclovir, and valacyclovir. These drugs exploit the fact that viral enzymes recognize certain molecules that the endogenous cellular enzymes do not, enabling the drugs to target only virus-infected cells. One of the most successful antiviral drugs, ACV, a guanine base attached to an acyclic sugar-like molecule, is used to block HSV lytic replication (Figure 4). ACV is highly specific because it targets two viral enzymes, the virus-encoded thymidine kinase (TK) and the viral DNA polymerase. The viral TK phosphorylates ACV to the monophosphate form while cellular enzymes phosphorylate it to the di- and triphosphate forms. The HSV DNA polymerase then incorporates the monophosphate form of ACV into the growing DNA chain, but the nascent DNA chain cannot be extended because

Figure 4 The chemical structure of acyclovir.

ACV lacks a 3'-hydroxyl group. Viral DNA synthesis is thereby inhibited. Minimal toxicity is observed because uninfected host cells lack the two enzymes needed for ACV incorporation into DNA.

ACV effectively blocks productive infection but does not affect latent infection. Resistance to ACV is uncommon except in individuals who are immunocompromised, such as AIDS patients, and those undergoing immunosuppression. In such cases, viral replication occurs at a high level, and mutant viruses that are resistant to ACV can arise.

Drugs such as ACV, when given promptly, have proved effective in reducing the mortality and morbidity associated with HSV encephalitis and ocular and neonatal infections. However, given the emerging link between HSV-2 and the acquisition and progression of HIV, a method of preventing HSV infection is needed. To this end, a number of different vaccine approaches have been investigated, including killed virus vaccines, subunit vaccines, and genetically engineered live virus vaccines. On the whole, killed virus vaccines have proven ineffective at preventing acquisition of HSV, and of two subunit vaccines that have been through human trials, only one showed some efficacy in a subgroup of patients. At this point, the use of replication-defective mutant viruses as vaccines appears to be the most promising approach. A current candidate, *dl*-529, has been rendered replication-defective through deletions in both U_L5 and U_L29 and has been shown to induce both high titers of neutralizing antibodies and strong cell-mediated responses.

Varicella-zoster Virus

Disease

VZV is the causative agent of varicella zoster or 'chickenpox', a common childhood disease with the highest prevalence occurring in the 4–10 years age group, and herpes zoster or shingles, a disease most often seen in older individuals. The virus is highly communicable, thought to enter susceptible individuals via the respiratory tract. From here, it spreads to the lymphoid system before producing the characteristic vesicular rash in the skin 10–21 days later. A fever and general feeling of malaise accompany the appearance of the rash. Most individuals become infected with VZV as children. However, approximately 10% of young adults remain susceptible. It should be noted that the incidence of varicella in the United States, particularly in children aged 1–4 years, has declined by approximately 85% since the introduction of a vaccine into the United States pediatric immunization schedule in 1995.

Following a primary infection, VZV establishes a latent infection in the sensory ganglia, with 10–20% of people experiencing a recurrent infection after several decades. Recurrent VZV infection manifests as a vesicular rash in the dermatome innervated by the latently infected ganglion and is referred to as herpes zoster or 'shingles'. It first presents with a prodrome, a painful burning sensation throughout the soon-to-be-affected dermatome. Several days later, the characteristic vesicular rash appears in the skin, which is generally accompanied by flu-like symptoms and can last up to 7–10 days. It is common for the burning, piercing pain to continue after the resolution of lesions in the skin, and in cases where pain persists for longer than 30 days after such resolution the patient is deemed to have post-herpetic neuralgia (PHN). PHN is generally self-limiting and most patients are pain-free by 6 months post-zoster, although pain can be significant until resolution.

The fact that herpes zoster is more common among the elderly and immunocompromised individuals supports the idea that the immune response plays an important role in determining whether VZV is able to reactivate from latency or not and whether symptomatic disease ensues. For those aged 20–50 years, the incidence of herpes zoster is around 0.25%, this rises to 0.8% in people aged over 60 and can reach as high as 50% in people who reach 85 years of age. Individuals with compromised immune systems are also at an increased risk of herpes zoster. People with HIV, leukemia, Hodgkin's and non-Hodgkin's lymphoma, and those who have undergone either bone marrow or renal transplants are at risk. It should also be noted that in immunocompromised individuals, the cutaneous rash is usually more extensive and widespread viremia is also common.

Virus and Biology

VZV shares the common herpesvirus virion structure of a core, containing a single copy of the 125 kbp linear, double-stranded DNA genome, surrounded by a nucleocapsid, a proteinaceous tegument layer, and an outer envelope. It also shares the ability to establish lifelong latent infections in the sensory ganglia with the other human alphaherpesviruses HSV-1 and HSV-2. However, unlike the HSVs that are able to replicate in cells from a wide range of hosts, VZV has a very narrow host range, restricted to selected cell types of

human and simian origin. Another difference between VZV and HSV relates to the spread of the virus through the host. HSV is generally confined to the epithelium infected during lytic infection and the neuronal cells within the sensory ganglia, where latency is established. VZV on the contrary has the ability to disseminate widely through the bloodstream of the infected host, infecting skin, mucous membranes, and visceral and nervous system tissues.

Replication

The infectious cycle of VZV is similar to that seen with HSV-1 and HSV-2. The virus uses surface glycoproteins, definitely gB and possibly gC, to attach to cellular surface glycosaminoglycans, such as heparan sulfate. Several other viral glycoproteins, gH, gE, and gI are also involved in the attachment and penetration process, following which the viral nucleocapsid, along with several tegument proteins, is transported to the nuclear surface and the viral genome is inserted into the nucleus. It is thought that, like VP16 during HSV infection, the VZV tegument proteins may be involved in initiating transcription of viral genes. The transcription of viral genes occurs in a sequential pattern with IE, E, and L genes, designated as such by the timing of their transcription. Each class of genes is transcribed in the nucleus, the mRNAs are then transported into the cytoplasm where they are translated, and the resulting proteins are then transported back into the nucleus. The IE genes are involved in the regulation of transcription of IE, E, and L genes and each VZV IE protein has homology to one of the HSV IE proteins, although the exact roles played by these proteins are not always homologous. The E proteins are involved in viral DNA replication, and the L proteins are generally structural, used to produce the capsids for progeny virions. The newly formed capsids travel out of the nucleus, becoming enveloped in the process, and are then transported to the cytoplasmic membrane where they are released from the infected cell. In cell culture systems, the entire process can occur in as little time as 8–16 h.

Pathogenesis

VZV is transmitted via inhalation of infectious respiratory secretions or skin-to-skin contact with infectious vesicular fluid and manifests as a vesicular rash throughout the skin 10–21 days later. Due to a lack of animal models for VZV, the pathogenesis of this virus was originally modeled on that of mousepox. Based on this model, it is thought that the inhalation of the virus enables infection of regional lymph nodes, resulting in a primary viremia that enables the virus to disseminate throughout the body, spreading to reticuloendothelial organs such as the liver. Within these organs, it is hypothesized that a phase of viral amplification occurs followed by a second round of viremia during which the virus is transported to the skin.

During primary infection, VZV is able to establish latency within sensory ganglia; VZV DNA is widely detected in the trigeminal ganglia and in many dorsal root ganglia of infected individuals. It is widely accepted that neuronal cells are the primary reservoir of latent virus, infected either hematogenously or by virus transported along neuronal axons from the skin via anterograde axonal transport. VZV latency differs from the situation during HSV infection in two main ways; first, unlike HSV infection, a number of VZV genes may be transcribed and translated while the virus is in a latent state, and second, VZV latency lacks the frequent episodes of asymptomatic reactivation seen with HSV infection. This later observation is thought to be due to the ability of the host immune response to quickly control reactivation events and maintain the virus in a latent state.

Many aspects of the host immune response come into play when dealing with a VZV infection. The innate response in epidermal cells plays an important role in slowing the spread of virus through the skin. NK cells and interferon (IFN- γ) also play a role in the innate defense against VZV infection, helping to contain the virus prior to the development of the adaptive response. In terms of adaptive immunity, VZV induces both cell-mediated and humoral immunity, with T cells thought to be particularly important in clearing infectious virus and helping to maintain VZV in a latent state.

Drugs and Vaccines

As with HSV, nucleoside analogues such as ACV and related drugs have been useful in treating VZV infections. In cases of varicella, oral ACV can be given to healthy individuals to reduce the severity of symptoms, while intravenous ACV is given to immunocompromised individuals to reduce the risk of disseminated infections. In cases of herpes zoster, ACV can be given to immunocompetent individuals to shorten the period of lesion outbreaks, the healing period, and the severity of acute neuropathic pain. Similarly for immunocompetent individuals, intravenous ACV can be used to shorten the period of disease and prevent disseminated infection.

VZV is the first HHV for which there is a licensed vaccine, a live attenuated virus vaccine derived from a clinical viral isolate known as the Oka strain. The Oka strain was attenuated by passage into guinea pig fibroblasts, producing a virus with reduced efficiency for replication in human skin. In clinical trials, a single dose of the vaccine was sufficient to induce seroconversion rates of 90% or greater in children 12 years and under and provided complete protection from disease in approximately 85% of exposures. The vaccine induces strong T cell responses with a single dose and also achieves high antibody titers when a second dose is administered and is now recommended for routine vaccination of infants and susceptible older children and adults in the United States. A recent study has also demonstrated that vaccination of healthy adults aged 60 years and older can significantly reduce the frequency and morbidity of herpes zoster, suggesting that a vaccination regimen in this population may also be useful.

The *Gammaherpesvirinae* Subfamily

Gammaherpesviruses are classified as such based on their ability to replicate in epithelial cells, establish latency in lymphocytes, and their oncogenic effects. Within the gammaherpesvirus subfamily, there are two genera: the *Lymphocryptovirus* (LCV) genus, which includes the human pathogen EBV, and the *Rhadinovirus* (RDV) genus, which includes KSHV. It is thought that the viruses within the LCV genus likely evolved from those in the RDV genus.

Epstein–Barr Virus

Disease

EBV, also known as HHV-4, is a widespread human pathogen with 90% of adults testing seropositive. In developing countries, most children are infected within the first 3 years of life, while in developed countries around 50% of individuals remain seronegative through childhood. It is estimated that 25% of people who then acquire EBV during adolescence or young adulthood will present with acute disease called infectious mononucleosis (IM), although it should be noted that childhood cases of IM are common in Asian populations and are possibly underdiagnosed in other parts of the world. Patients with IM can present with symptoms ranging from a mild and transient fever to a period of malaise and pharyngitis lasting several weeks. This period of EBV disease is closely linked to the emergence of the cytotoxic T cell response to infection, and it is widely accepted that IM is mostly an immunopathologic disease, with the proinflammatory cytokines secreted by active T cells thought to be responsible for many of the IM symptoms. In a small subset of patients, IM is poorly controlled and can lead to more severe, possibly fatal, outcomes. Males with X-linked lymphoproliferative (XLP) syndrome are highly sensitive to EBV infection. In these patients, primary EBV infection results in severe IM-like symptoms and can rapidly result in mortality, thought to be due to an uncontrolled T cell response to infection. Virus-associated hemophagocytic syndrome (VAHS) and chronic active EBV infection (CAEBV) are two other serious outcomes of EBV primary infection. Both involve EBV infection of T cells, resulting in virus-driven proliferation of these cells (much like the proliferation of B cells during a classical primary infection). The infected T cells release huge amounts of proinflammatory cytokines, which results in hemophagocytosis, where macrophages begin phagocytosing red blood cells, platelets, leukocytes, and other cells. The risk of mortality with either syndrome is high.

Following primary infection, EBV establishes a latent infection in B cells, which is generally maintained as such for the life of the host with no clinical manifestations. However, this is not always the case, and EBV is associated with a number of different human malignancies. In immunocompetent individuals, usually following several decades of EBV latency, EBV is associated with the development of certain types of Hodgkin's lymphoma, several B-lymphoproliferative lesions, T cell and NK cell nasal lymphomas, and gastric and nasopharyngeal carcinomas. In immunocompromised individuals, the virus is capable of rapid tumor development, with some cases of tumorigenesis evident within months of EBV infection. In transplant settings, a link has been demonstrated between EBV and posttransplant lymphoproliferative disease (PTLD), with EBV association as high as 100% in early onset cases and 80% with late onset cases. AIDS patients show a heightened risk of B cell lymphoma with approximately 50% linked to EBV, and most settings involving immunosuppression have demonstrated a link between EBV and smooth muscle cell tumors. EBV is also associated with endemic Burkitt's lymphoma (BL), the most common childhood cancer in equatorial Africa which is geographically linked to areas of holoendemic malarial infection, although the mechanisms through which EBV contributes to BL are not fully understood.

Virus and Biology

EBV shares the common herpesvirus virion structure and has a 184 kbp genome. There are two strains of the virus, types 1 and 2 or types A and B, which circulate in most populations. Individuals can be infected with both types and this is a common occurrence in immunocompromised individuals. Type 1 is generally more prevalent in developed countries while type 2 is dominant in equatorial Africa and New Guinea. The main differences between the two strains are seen in the nuclear protein genes that encode EBV-coded nuclear antigen (EBNA)-LP, EBNA-2, EBNA-3A, EBNA-3B, and EBNA-3C.

Replication

EBV is known to infect both B cells and epithelial cells during primary infection, with infection of epithelial cells thought to result in a lytic infection and infection of B cells thought to generally result in a latent infection. In B cells, the virus binds to CD21 and MHC class II on the surface of target cells using glycoproteins in the virus envelope. A cell surface receptor for epithelial cell infection has yet to be found, and it is hypothesized that virus may be transferred to epithelial cells directly from lytically infected B cells. The entry of virus into each cell type differs in that virus enters B cells via the endocytic pathway while virus entering epithelial cells does so at the cell surface, in both cases viral glycoproteins are involved in facilitating fusion and entry of the virus into the target cell. Following entry of the virus into the target cell, the nucleocapsid is transported to the nucleus into which the viral genome is inserted.

If a lytic infection ensues, as is thought to occur in epithelial cells *in vivo*, the sequential expression of IE, E, and L genes, common to herpesviruses, is seen. The IE proteins are primarily involved in activation of E gene expression, the E proteins are primarily involved in viral DNA replication, while the L proteins are involved in the production of progeny virions. At this time, it is thought that newly formed nucleocapsids initially acquire an envelope at the inner nuclear membrane, are de-enveloped as they are released into the cytoplasm, and then reacquire an envelope as they bud through the plasma membrane.

It is widely accepted that initial infection of B cells results in a latent or persistent infection. In fact, *in vitro* studies demonstrated that infection of B cells with EBV resulted in a latent infection that was capable of causing perpetual B cell proliferation, helping to confirm the oncogenic properties of EBV. During latency, the viral genome is maintained in the nucleus of the infected cell in an episomal form with variable levels of gene expression possible. There are four different forms of EBV latency: latency 0, I, II, and III. These stages are classified as such based on the level of expression of the EBNA and latent membrane proteins (LMPs), with latency 0 having no viral antigens expressed and latency III having all latency proteins expressed.

These different forms of latency are used by the virus to ensure the maintenance of the viral genome within progeny B cells, and as such the virus uses cellular differentiation controls to determine which level of latency is required at any given time. For example, during a primary infection, EBV is present in infected B cells in latency III form, and the expression of viral genes at this stage is used to drive the proliferation and differentiation of these cells into a latently infected memory pool. Once the memory pool is established, and in order to prevent further detection by virus-specific cytotoxic T cells, EBV switches off all gene expression, thus entering latency 0. At times when memory B cells are induced to divide by homeostatic signals, the virus reactivates to latency I to ensure the viral genome is not lost during such cell division. In this way, the virus is able to establish a balance between avoiding immune detection and maintaining the viral genome. At times of cell proliferation, the viral EBNA-1 protein tethers the viral chromosome to the cellular chromosome to ensure maintenance of the viral genome within daughter cells.

Pathogenesis

EBV infection is transmitted via the oral route and is generally asymptomatic. As such, knowledge of the primary infection has come from the study of IM. These individuals shed virus in saliva and throat washings. However, the source of this virus remains contested. It is generally assumed that because B cell-deficient individuals show no sign of EBV infection in the throat, initial infection of a naïve host is B cell-dependent. However, it is becoming more widely accepted that epithelial cells may also be sites of viral replication, with studies suggesting that virus bound to the surface of a B cell is highly efficient at infecting epithelial cells. Interestingly, recent evidence further suggests that virus released from B cells is defective for B cell infectivity but shows enhanced infection of epithelial cells, while virus released from epithelial cells has the opposite phenotype.

EBV establishes a latent infection in B cells at the site of primary infection, the tonsillar tissue. Studies suggest that latently infected B cells express a memory phenotype, and it has been proposed that infection of naïve B cells with EBV mimics the process of B cell differentiation, resulting in activation and proliferation of the infected cell population, and thus the production of an expanded pool of latently infected memory cells. It is generally accepted that the cell-mediated immune response brings the proliferating B cells under control. The memory pool of latently infected B cells, which circulates through the body, is able to disperse the latently infected cells throughout the lymphoid system. Individuals latently infected with EBV will have peripheral blood B cells that harbor virus and, following clearance of the primary infection, these individuals will continue to shed low levels of infectious virus via the oral cavity. This virus comes from the latent B cell reservoir. It is thought that memory B cells containing latent virus may undergo reactivation when they receive an activation signal, and that such cells, which localize near mucosal surfaces, would be capable of transmitting lytic virus to epithelial cells where viral replication and subsequent shedding can occur.

In a healthy individual with an intact immune system, EBV persists in this form for the life of the host with no clinical manifestations. The latent pool is constantly maintained by the virus moving forward and backward through the various forms of latency as required, and infectious virus is sporadically shed from the oral cavity with the potential of infecting other susceptible hosts. However, when immune suppression occurs, either through disease or drug intervention, this balance is destroyed and the individual is put at risk of EBV-associated disease.

Drugs and Vaccines

To date, attempts to develop preventative vaccines against EBV have been largely unsuccessful. The finding that the major viral envelope protein gp350 was the dominant target of the neutralizing antibody response led to attempts to develop a gp350 subunit vaccine. However, some evidence suggests that neutralizing antibodies alone are not sufficient to protect against EBV, with clinical trials showing that the gp350 subunit vaccine failed to prevent primary infection, although it was able to reduce the incidence of IM symptoms. It is now widely believed that an integrative approach is required, where a vaccine to prime the antibody response (such as the gp350 subunit vaccine) would be given in combination with a vaccine aimed at priming the CD8⁺ T cell response. However, it should be noted that even this integrative approach would probably be most successful at limiting rather than preventing infection.

In parallel with efforts to design a preventative vaccine, efforts are also being aimed at developing immunotherapeutics for EBV-associated malignancies. Current strategies being developed include adoptive transfer of activated T cells specific for viral antigens expressed on EBV-associated tumors and the development of vaccines that can boost the host T cell response to these same antigens. Both strategies are aimed at increasing T cell recognition and subsequent destruction of EBV-associated tumors.

Kaposi's Sarcoma-Associated Herpesvirus

Disease

KSHV, also known as HHV-8, is the most recently identified HHV. The virus was originally identified because of its association with Kaposi's sarcoma (KS), an endothelial neoplasm. It was later recognized as a member of the LCV genus within the gammaherpesvirus subfamily of herpesviruses.

Infection rates with KSHV in the United States and in Europe are relatively low with approximately 3% of the population infected. In Africa, a different picture emerges, with KSHV reaching endemic rates of infection of between 40% and 60%. The various strains of KSHV can be divided into four major groups or clades: A, B, C, and D, with each virus within a given clade sharing a single common ancestor. A and C tend to cluster together and are more prevalent in Europe and in the United States, B is the most commonly isolated in infected individuals in sub-Saharan Africa, and D is the dominant clade seen in South Asia and Australia. The pattern of distribution and the evolutionary relationship between viruses in the different clades suggest that KSHV entered the human population at about the time when modern man emerged in Africa, with the different clades being produced as different groups moved out of Africa to Europe and Asia, respectively. The fact that the distribution of these clades seems to have been maintained over millions of years also suggests that, particularly in areas of high seroprevalence, transmission of KSHV is primarily familial, moving vertically from parent to child and horizontally between different members in a family unit possibly via salivary exchange. It should be noted that in areas of low seroprevalence, such as Europe and the United States, the pattern of infection appears to follow that of a sexually transmitted disease, and virus has been successfully isolated from both saliva and genital secretions.

The most common malignancy associated with KSHV is KS. KS is a complex, angioproliferative, and inflammatory lesion. It was historically a disease of elderly Mediterranean men until it emerged as the most common neoplasm seen as a complication of HIV/AIDS. In both settings, the disease is a slow progressing malignancy, although it can result in death in AIDS patients if organ involvement is present. Unlike a classical tumor, KS lesions contain many different cell types with the driving cell being a KSHV-infected spindle cell (an elongated endothelial cell). The spindle cells produce proinflammatory and angiogenic products and may actually require factors released from proinflammatory cells for survival and growth. It is possible for KS lesions to be locally or systemically invasive, requiring chemotherapy or radiotherapy.

While strong evidence suggests that KSHV is necessary for KS development, it is certainly not sufficient. Within the general population, only 1 in 10 000 infected individuals will develop KS annually. Therefore, it is assumed that there are other cofactors involved in the development of KS. In AIDS-related KS, the assumption is that HIV infection is the cofactor. It has been proposed that an HIV protein may act as a growth factor for KSHV or that the immunodeficiency seen during HIV infection may enable KSHV to disseminate more widely through the host, increasing the chances of endothelial cell infection. The cofactor in non-AIDS-related KS remains unknown.

Along with KS, KSHV has been implicated in two B cell diseases, primary effusion lymphoma (PEL) and Castleman's disease. PEL is a rare disease seen in end-stage AIDS patients and is characterized by proliferation of B cells primarily in body cavities such as the pleura, pericardium, and peritoneum. Unlike KS, PEL is a classical malignancy with every cell in the tumor harboring KSHV DNA. Castleman's disease is a rare, lymphoproliferative lesion that is seen in both HIV-positive and HIV-negative individuals. In HIV-negative individuals, Castleman's disease generally presents as a benign tumor localized to a single lymph node. This form of Castleman's disease does not involve KSHV and is usually treated by excision of the involved tissue. Multicentric Castleman's disease is a more aggressive, systemic illness characterized by sustained fever, sweats, and weight loss. This form of Castleman's disease is seen with increased frequency in patients with AIDS and, in this setting, is almost always linked to KSHV infection.

Virus and Biology

KSHV shares the standard herpesvirus virion structure described above. The virion contains a double-stranded linear DNA genome of between 165 and 170 kbp in length that contains four blocks of highly conserved genes, many of which encode replication proteins common to alpha- and betaherpesviruses. The genome also encodes several small noncoding miRNAs, the function of which remains unknown, several of which are expressed during latency and one of which is expressed during lytic infection.

Replication

The replication cycle of KSHV follows a pattern similar to that seen with the other herpesviruses and thus will not be discussed in detail here. Virus attachment and entry are facilitated by several viral glycoproteins, following which the viral genome and several tegument proteins are delivered into the nucleus of the infected cell. If, at this point, the virus enters the lytic cycle, the sequential expression of over 90 viral genes is initiated. These genes are divided into IE, delayed early (DE), and L genes. The mechanism of KSHV egress has yet to be fully elucidated.

Despite the obvious ability of the virus to induce a lytic infection, as demonstrated by the intermittent shedding of virus from infected individuals, studies in cell culture systems suggest that the default pathway in KSHV infection is latency. From *in vitro* work, it appears that only a small number of cells (1–3%) will enter the true lytic pathway and that this will subside following several days of infection. In the majority of cells, a defective version of lytic infection arises, which is quickly terminated and latency established.

In these cells, several lytic cycle genes are expressed during the first 12 h of infection. However, the expression of these genes ceases by 24 h postinfection and the genes are not expressed in their correct sequential order, thus providing evidence of the defective nature of this 'lytic' infection. Latency is then quickly established in these cells. The role that the faulty lytic infection plays in the overall virus infection remains unknown, although it has been proposed that the transient expression of some of the viral immune evasion mediators may be beneficial during the early stages of infection.

Once latency is established, the viral genome is replicated as an episome. The viral LANA protein tethers the viral episome to the cellular chromosome so that the viral genome is distributed to progeny cells during cell division. At this time, only a few of the 90-plus viral genes are expressed. However, the exact roles that these proteins play during the latent infection still require much investigation. Work to date would suggest that they may be involved in maintenance of the viral genome in dividing cells, prevention of apoptosis and, surprisingly, upregulation of proinflammatory responses. The switch from the latent to the lytic phase of infection is thought to be facilitated by the so-called lytic switch protein, known as RTA. This protein is a viral transcriptional activator that is capable of inducing lytic gene expression on its own, but becomes even more efficient when bound to one of several different HCFs. In experimental systems, deletion of RTA prevents both spontaneous and chemically triggered induction of the lytic cycle.

Pathogenesis

Primary infection of a susceptible host is followed quickly by the establishment of latency, primarily in B cells. In most individuals, the latent infection is asymptomatic and is accompanied by intermittent, clinically silent viral reactivation that enables shedding of virus in the saliva. Given the apparent absence of an extended primary lytic infection, asymptomatic reactivation during latency would appear to play a major role in virus transmission.

The exact role of KSHV in the pathogenesis of KS is currently unknown. It appears that both latent and lytic stages of infection are important, with KSHV latency much less potent than EBV latency at inducing cell immortalization. Most KS spindle cells are latently infected but a small percentage demonstrates lytic infection. It would appear that this low level of lytic replication is important in the development of KS, possibly enabling the reinfection of spindle cells that have lost the KSHV genome, providing a reservoir of newly infected cells to replace cells within the tumor mass that have died, or even providing some of the inflammatory and angiogenic signals that play a role in KS pathogenesis.

Drugs and Vaccines

Ganciclovir may have a role in preventing KSHV spread and KS development but does not affect an established tumor. Because in most individuals, the immune response is adequate to control the virus and prevent virus-associated disease, it is common with immunocompromised patients to treat the underlying cause of immunosuppression or to attempt to treat the malignancy itself as well as the viral infection.

The *Betaherpesvirinae* Subfamily

The betaherpesviruses are characterized by a restricted host range, a long productive cycle, and the ability to establish latent infections in secretory glands, lymphoreticular cells, and kidneys. The betaherpesviruses have the highest level of evolutionary and genetic diversity of the three herpesvirus subfamilies, which can make the use of animal models to study human pathogens within this subfamily difficult. There are four genera within the betaherpesvirus subfamily: the cytomegaloviruses, the muromegaloviruses, the roseoloviruses, and the probosciviruses (which has only a single member).

Human Cytomegalovirus

Disease

HCMV is a ubiquitous human pathogen, infecting those in developing countries in their youth and those in developed countries across a slightly wider timeframe. In most individuals, HCMV causes an asymptomatic infection, with disease generally only seen in those unable to mount a cellular response to infection, such as neonates or individuals with some form of immunosuppression. As is characteristic of herpesviruses, HCMV establishes a latent infection within the host, although interestingly this is also accompanied by what can be called a chronic infection, with infected individuals shedding virus sporadically from their bodily fluids for life.

HCMV can be classified as an opportunistic pathogen, only causing disease in situations where the immune response is severely compromised (such as in AIDS) or absent (such as congenital infection). In most healthy individuals, infection with HCMV is clinically silent, although it should be noted that in a small number of cases a short bout of fever and malaise can occur, similar to the mononucleosis caused by EBV.

Congenital Infection

Transmission of HCMV from mother to fetus or newborn is a very common occurrence and can occur via three routes: transplacental, intrapartum, and via human milk. HCMV is the only herpesvirus known to exhibit natural transplacental transmission, and it is this congenital route of transmission that causes serious morbidity. That said, intrapartum and transmission via breast milk, while not associated with the morbidity of congenital infections, both play an important role in viral epidemiology. These newborn children infected with HCMV will continue to shed virus capable of infecting susceptible hosts for many years after the primary infection.

Congenital infection can occur when the mother has either a primary or reactivated infection during pregnancy, with evidence from those undergoing a primary infection suggesting that transmission to the fetus can occur in 20–40% of cases. Although less than 1% of live births involve a child with congenital HCMV, the long-term sequelae for these children make it a serious disease, with HCMV estimated to be the leading cause of infectious brain damage in the United States. Approximately 5–10% of those born with a congenital HCMV infection will be symptomatic, showing clinical manifestations such as hearing loss, seizures, jaundice and brain abnormalities, with long-term sequelae such as mental retardation, cerebral palsy, and impaired vision. In 10% of cases, symptomatic congenital HCMV infection will be fatal. Even the 90% of congenitally infected children born without symptoms remain at risk of long-term CNS sequelae such as hearing loss.

Infection in an Immunocompromised Host

Patients with compromised or suppressed immune systems are at greater risk of CMV-associated disease than healthy individuals, with the severity of disease often matching the level of immunosuppression. In patients with HIV or those undergoing solid organ or hematopoietic stem cell transplants, HCMV can disseminate into a number of different organs, causing clinical manifestations such as pneumonitis, retinitis, and hepatitis. In organ transplant patients, HCMV has also been shown to cause dysfunction of the transplanted organ and put the patient at greater risk of fungal and bacterial infections. The thorough screening of transplant patients and the use of antivirals in this setting and HAART in the HIV setting has reduced the morbidity and mortality associated with HCMV infection in immunocompromised individuals.

Virus and Biology

Compared to the other HHVs, HCMV is a very large virus. With a genome between 196 and 241 kbp, the virus encodes in excess of 166 gene products (less than half of which are conserved in all betaherpesviruses), and while HCMV shares the common herpesvirus virion structure, the actual size of the virions is larger than that of the other HHVs.

Replication

The replication cycle of HCMV follows a similar pattern to that described for the other herpesviruses. The virus uses heparan sulfate as an initial binding receptor on target cells and then enters the cell via either fusion of the viral envelope with the cellular membrane or the endocytic pathway. The viral genome is released into the nucleus and the lytic viral genes are expressed in a sequential manner: IE, DE, and L. Strong evidence argues that HCMV undergoes a two-stage envelopment/de-envelopment/re-envelopment process in order to exit an infected cell. Newly synthesized nucleocapsids are enveloped as they pass through the inner nuclear membrane and then deenveloped as they pass through the outer nuclear membrane. The envelope-free nucleocapsid is thus released into the cytoplasm where it reacquires an envelope at the ERGIC membranes before being transported out of the infected cell via the cellular exocytic pathway.

In terms of replication, the main difference between HCMV and other HHVs is the length of the replication cycle. DE gene expression begins at 6 h postinfection and continues through 18–24 h when viral DNA synthesis is initiated. From initial attachment to the initiation of progeny virion release, the complete infectious cycle takes between 42 and 78 h. During this time, the virus has a profound effect on the infected cell, blocking IRF-3 activation, IFN signaling, and apoptosis responses and interrupting the cell cycle in such a way that infected cells are able to survive for several days of productive infection.

Pathogenesis

In an immunocompetent host, HCMV infection is generally asymptomatic. Primary infection is usually initiated in the mucosal epithelium following direct contact with infectious secretions from another individual, aerosol transmission does not occur. A systemic phase of infection then follows with a leukocyte-associated viremia. Animal models with murine CMV (MCMV) suggest that the virus uses immature leukocytes from the bone marrow to facilitate dissemination to the salivary glands, kidneys, and other tissues. This systemic phase of infection is associated with high levels of persistent viral shedding in the saliva, urine, breast milk, and genital secretions and continues for a long time after the onset of the adaptive immune response. It can last for months in adults

and for years in young children, supposedly due to a less effective cellular immune response in younger patients. The ability of the virus to persist in the face of the cellular immune response is thought to be due, in part, to the fact that more than 25 viral genes have been found to play a role in modulating the host response to infection.

When virus is cleared following primary infection, HCMV is maintained in a latent state in hematopoietic progenitor cells (HPC). However, unlike the human alphaherpesviruses, this latent infection can be accompanied by what can be called a chronic infection in epithelial cells of the salivary glands and kidneys, which results in sporadic shedding of virus in the bodily fluids for the life of the host. Reactivation of virus from latency, as opposed to the sporadic viral shedding achieved by the persistent infection in the salivary glands and kidneys, seems to be an issue only in situations of immunosuppression.

Immune responses to HCMV are well maintained for years beyond the primary infection, at levels not seen with other herpesviruses or persistent infections. Innate immune responses such as IFN and NK cells are important during the early stages on infection and may play a role in containing the infection until the adaptive immune response develops. T cell responses appear to be of greater importance than antibody responses, although in certain settings antibodies play a crucial protective role. Despite the persistence of the primary viremia in the face of an active cellular immune response, the fact that viral reactivation is only seen in cases of immunosuppression suggests that the immune response plays an important role in helping to maintain the virus in a latent state and preventing CMV-associated disease.

Drugs and Vaccines

There are currently four drugs approved for the treatment of HCMV infection in immunocompromised individuals: Ganciclovir, Valganciclovir, Foscarnet, and Cidofovir. All four have been shown to reduce or eliminate viremia, reduce viral shedding, and prevent or control CMV disease. However, due to risks of severe toxicity, the drugs are only used when a patient is at risk of serious disease. At this time, no drugs are approved for the treatment of congenital CMV, although a small Ganciclovir trial did produce some positive results.

Given the seriousness of congenital CMV infection and the difficulty in preventing maternal infections, a preventative vaccine would have a large public health benefit. Several different vaccine approaches have been tested to date. However, a CMV vaccine is yet to reach the market. Strategies that have reached clinical trials have included a live attenuated vaccine, a gB subunit vaccine, a canary pox vector expressing CMV gB and pp65, and a DNA vaccine with antibody and CTL epitopes. Several of these vaccines have shown promising results in inducing strong immune responses.

HHV-6 and HHV-7

Disease

HHV-6 was first isolated in 1986 and is classified into two variants, A and B. HHV-6B is the major causative agent of exanthem subitum (ES), while HHV-6A has not been clearly linked with any disease. HHV-7 was first isolated in 1990 and is also a causative agent of ES as well as being associated with febrile convulsions in young children. Both HHV-6 and HHV-7 are ubiquitous pathogens, with greater than 90% of adults seropositive for both.

ES or roseola is a classical childhood disease (sixth disease). It initially presents as a fever lasting for 3–4 days. As the fever clears, a rash appears, first on the trunk and hands and then on the lower limbs, lasting several days. HHV-6B is the major cause of ES, with the magnitude of viral replication correlating with the severity of disease. HHV-7, while also a cause of ES, has a lower frequency of disease as compared to HHV-6B. It is possible for children to have successive bouts of ES caused by one virus and then the other. Most cases of ES are benign and are associated with other symptoms such as diarrhea, cough, and febrile convulsions. However, it is possible for HHV-6 infection to result in encephalitis, meningitis, and hepatitis, which can be fatal.

Following primary infection, both HHV-6 and HHV-7 persist in a latent state. As with other herpesviruses, reactivation is generally only a problem in situations where the immune system is compromised. In bone marrow transplant recipients, asymptomatic HHV-6 reactivation is common. However, reactivation has also been linked to bone marrow suppression, encephalitis, colitis, pneumonitis, and graft-versus-host disease. In solid organ transplant recipients, HHV-6 reactivation has been associated with kidney rejection.

Virus and Biology

HHV-6A, HHV-6B, and HHV-7 are members of the roseolovirus genus of the betaherpesvirus family, sharing the common characteristics of growth in T cells, high prevalence, and association with febrile rash illness. HHV-6A and HHV-6B are closely related but actually meet the requirements for recognition as two separate viruses – they differ in cell tropisms, interactions with cells and the immune system, DNA sequences, and epidemiology. As with the other human betaherpesvirus, HCMV, both HHV-6 and HHV-7 have protracted replication cycles and share some beta-subfamily-specific genes.

The virion structure of HHV-6 and HHV-7 follows the common herpesvirus structure of a dsDNA genome within an icosahedral capsid that is surrounded by a tegument layer and finally a lipid bilayer envelope. HHV-6 has a genome of up to 170 kbp, while the HHV-7 genome is 145 kbp in length.

Replication

HHV-6 and HHV-7 have a similar replication cycle to those of the other HHVs. Following virus attachment and entry, the viral genome is delivered to the nucleus where viral gene transcription is initiated in a sequential manner: IE, E, and L. Egress of newly formed virions from the infected cell follows the same path as that used by HCMV: envelopment/de-envelopment/re-envelopment.

Pathogenesis

Transmission of HHV-6 and HHV-7 is not fully understood. It is thought that transmission during infancy occurs horizontally, possibly via saliva during close personal contact. However, it is also thought that the viruses can be transmitted across the placenta, during delivery, or even intrauterine. The exact site of primary infection is also yet to be determined. It is currently thought that infection is initiated through respiratory pathways, however, the exact cells that are infected are not known.

Both HHV-6 and HHV-7 establish latent infections within their hosts. It is thought that HHV-6 establishes latency in monocyte or macrophage cells and certain stem cells. HHV-6 DNA and antigens can also be detected in a range of other sites including the saliva, brain, and lung, suggesting a concurrent persistent infection. HHV-7 establishes a latent infection in CD4⁺ T cells while maintaining a persistent infection in the salivary glands and a variety of other tissues.

Drugs and Vaccines

Several drugs approved for use against CMV have been shown to be effective against HHV-6 and HHV-7 *in vitro*, these include Ganciclovir, Foscarnet, and Cidofovir. IFN- α and IFN- β have also been shown to inhibit HHV-6 replication *in vitro*. However, no drugs are currently approved for use in the treatment of HHV-6 or HHV-7 infection.

Historical Plague ☆

Overview

The history of bubonic plague generates considerable popular and scientific interest, but it is more difficult to assess how plagues independently affected the course of human events. Within the enormous body of work devoted to this broad topic, we can identify patterns of scientific concern with past plagues, often occurring when newly available scientific technologies or theoretical perspectives invite reconsideration of long-unsolved questions. Plague scientists themselves made bold historical claims during the opening years of 20th century, after a new pestilence appeared in East Asian port cities in the mid-1890s. The disease was highly lethal and its victims had classic inguinal and axillary lymph node swellings, which bore strong similarities to historically famous epidemics in Europe centuries before. At the same time historical accounts did not readily explain why new outbreaks of a nearly-banished disease now suddenly appeared. Like the earlier, intermittent outbreaks of cholera in the 19th century, and the 'Russian influenza' of 1889–91, this plague became a pandemic, and it quickly spread to every continent except Antarctica.

An impressive array of early investigators from many different nations unraveled the basic biological and ecological parameters of the disease before 1900. While the clinical description of human plague infection seemed a secure point of contact between past and present, the biology of the pathogen did not reflect plague's reputation as a human contagion. Instead plague principally involved rodent populations and was spread by means of their fleas, evidence that formed a central paradox within plague history for the next century. Classically educated European scientists were especially anxious to link historical narratives of catastrophic past mortality events to the evidence of plague in modern times. Most also wrote histories that celebrated European scientific or cultural triumphs, explaining the defeat of a fierce ancient foe rather than confront the unpredictable reappearances of great pandemic mortality. Drawing upon public health tradition, plague histories touted generally helpful contagion-based epidemic containment strategies as responsible for plague's successful control in centuries past. To explain why earlier plagues were so deadly, the scientists' histories credited the large-scale urban environmental sanitation achievements that western industrial nations initiated during the 19th century. Non-western cultures and peoples were seen as plague-prone because these peoples did not embrace similarly high standards of public and private cleanliness.

The next generation of plague scientists also produced influential, comprehensive summaries of plague history. These works offered a parallel summary of plague biology and advanced an ever-more detailed historical framework that singled out two massive historical plague epidemics in the past, events caused by trade with regions outside Europe. The earliest recorded pandemic coincided with the reign of Byzantine Emperor Justinian in late antiquity; the other began with the 'Black Death' of 1347–53, understood as the first in a series of recurrent plagues in Europe. All of these works claimed that plague subsequently retreated to the margins of the Western world, from whence it came, lingering longer in medieval Europe than in the pandemic of late antiquity. These authors well understood that plague ordinarily appeared in remote rural foci, and so these histories acknowledged that the disease displayed different epidemiological characteristics in previous pandemics.

Historians in the post-war era relished the wide-ranging challenges that scientific histories of plague presented. Many turned to the retrieval and study of non-narrative historical sources; others provided more detailed background analysis of plague literature. The shortcomings of older science-driven plague history came to the foreground from the 1960s to 90s, as historians examined a wider range and depth of evidence about individual plague outbreaks, or focused on patterns of plague experience in particular locations or time periods. By the end of the century prominent historians of medicine argued that it was impossible to make any modern diagnosis from the observations of persons writing before the germ theory era. Early in the current century, several influential historians of the Black-Death epidemic and its recurrences even denied that *Yersinia pestis* could ever have existed in Europe, believing plague's requisite hosts and vectors were non-European species. Moreover, this argument went, whatever disease caused the extraordinary mortality crises of the later Middle Ages and early modern centuries, it was spread person-to-person, thus contagious, and was disseminated at a great a speed across Europe, distinctly unlike a vector-borne infection.

Two broad avenues of inquiry now lead plague history in new directions, because we now know with certainty that *Y. pestis* was present in Europe in both earlier pandemics. Once again, scientific work on plague's history intensifies. Recent genetic and archaeological methodologies permit the retrieval of ancient pathogen DNA from human remains, and multidisciplinary computerized data analysis can assemble and compare local historical and environmental evidence in ways not previously possible. Secondly, many historians have shifted away from small-scale microhistorical studies to regional and global history, wishing to prioritize geographically and culturally more inclusive analysis. *Yersinia pestis* confirmed, the older view that European responses to plague were either progressive or successful responses to plagues must be revised. Why plague disappeared from Europe becomes again an open question. New historical research overturns long-standing assumptions about the experience of non-Europeans, views no longer acceptable. Other work from social scientists and archaeologists helps to document the patterns and magnitude of

☆ *Change History*: November 2016. AG Carmichael prepared a new text, replacing the existing entry of 2014.

discrete mortality events and move analysis beyond a reliance on views expressed by literate witnesses. Such research frameworks invite comparison of mortality crises in human communities. Some historical evidence can be aggregated and analyzed with very large data sets, opening the prospect of multidisciplinary, multi-scale investigation of past plagues.

Plague History from Plague Science: 1890s–1970s

Alexandre Yersin first isolated the plague pathogen *Yersinia pestis* in Hong Kong, 1894, naming it *Pasturella pestis* to honor Louis Pasteur. Hong Kong's plague became the opening drama to what came to be called the 'third pandemic'. Throughout the 19th century other plague outbreaks had occurred in southern Russia, southwestern China and some remote regions of Manchuria, attracting venture-some scholars to travel to outbreak sites, then publish their direct local observations. During the 1890s plague spread quickly and directly from southwestern Chinese uplands, to Hong Kong, to southern and southeastern Eurasian port cities, then on to many previously unaffected regions around the globe. Telegraphed news of plague fed the fears and anxieties of people in western industrializing nations, and journalists built on expose's of other deadly epidemics that circuted the globe: influenza in 1889–91, cholera in 1892. With international attention trained on their actions British local administrators in Hong Kong feared political unrest as much as disruption to trade, and thus used draconian sanitation procedures to contain plague, measures focused on the desperately poor area where most of the native Chinese labor force lived. Similarly officials in nearly every port city where plague first appeared over the next two decades similarly tried to control plague by identifying politically powerless racial, cultural and ethnic groups as the primary threat to urban health and good order. The political and material costs of such panic responses were enormous, and became increasingly difficult to justify alongside the steady production of new bacteriological knowledge about plague.

By the late 1890s, urban rats were identified as the primary plague carriers and their fleas shown to transmit the bacillus to both rats and humans. By 1910, public health authorities in most nations had gradually adopted policies informed by bacteriological plague research, involving both mammalogists and entomologists in their efforts to interrupt rat/flea plague transmission. By the time Western Europe swept the whole world into war, anti-plague procedures targeted commensal rodents and redesigned disinfection protocols, particularly at harbors and on large maritime vessels. In 1910–11, the combined research of Russian imperial commissions and a young Cambridge-educated Chinese investigator, Wu Liande [or, Wu Lien-Teh] verified plague transmission from Manchurian marmots to hunters and trappers in the sparsely settled Chinese-Russian frontier, shifting explanations about plague persistence and control away from an exclusive focus on urban *Rattus* species. Although Wu and others blamed the behaviors and habits of migrant laborers, specifically southern Chinese 'coolies', for spreading plague, from this point forward an important component of ongoing plague research investigated endemic plague transmission in remote regions, involving many different mammalian hosts and insect vectors.

Plague histories of the early 20th century struggled to follow the pace of plague science, as is evident from the famous 1911 edition of the *Encyclopaedia Britannica*. The 1880s entry was reprinted, then a second entry, written by new authors, was added to summarize evidence harvested since the mid-1890s. To explain why an ancient threat suddenly reappeared and spread globally, the authors of the updated addendum stressed the disappearance of plague from western Europe during the 17th and 18th centuries, setting up a view that has dominated much plague history ever since: European nations designed and implemented policies that banished plague.

During the first half of the 20th century a dominant multi-century history of plague emerged, well supported among participants in infectious disease research and control but profoundly Eurocentric. By the interwar decades the world's biomedical community had concluded that bubonic plague best accounted for the epidemic in Constantinople during the reign of Emperor Justinian (in the 540s ce), the peerless Black Death mortality wave, 1347–1353, the great plague of London in 1665–66, and the massive 1720–22 plague of Marseille. Vivid and distinctive historical accounts of victims with painful swellings around groin, axilla, or cervical lymph nodes linked the two earlier plague eras to the clinical features of victims in the third pandemic. Literary accounts of pestilences from medieval and early modern Europe were also used to support a view that progressive medical and public health ideas conquered recurrent plague, even though the first pandemic's retreat could not be similarly explained, and these specific measures failed in the third pandemic everywhere they were used without targeted rat and flea control.

Centering plague's pre-modern past around literary accounts led to histories that disproportionately reflected urban experience and even swayed the direction of some important investigations. Seeing epidemic plague as an urban phenomenon, investigators in British India produced a series of influential studies, 1897–1915, which identified a ubiquitous commensal rodent, *Rattus rattus*, and one particular cosmopolitan flea, *Xenopsylla cheopis*, as the principal culprits in human plague outbreaks. Some part of this work transmitted a stigmatizing characterization of the 'Indian rat', the 'Oriental rat flea', and the plague itself as a 'tropical' disease, views that deviled plague history for the rest of the 20th century. Meanwhile, two classic studies based on evidence gathered during the 1906 plague in Mumbai (then Bombay) became lasting tenets of plague epidemiology. In 1914, A.W. Bacot and C.J. Martin, both at the Lister Institute in London, claimed that *X. cheopis* was the flea responsible for human plague epidemics because it fed indifferently on humans and rodents and because their research showed that it became 'blocked', unable to feed, when infected with the plague bacillus. A starving blocked flea fed frantically, accelerating plague transmission to new hosts. The 1927 study of A.G. McKendrick and W.O. Kermack instead devised a mathematical model to explain the spread of human-to human infectious diseases, work known in introductory epidemiology texts as the SIR (susceptible–infected–recovered/removed) model. Unfortunately they used human clinical plague data collected in 1906 Mumbai to illustrate the model, thus nurturing a view that human plague transmissions were often contagious or airborne.

Description of great epidemics in Europe's past was not the only available perspective on prior plagues. For nearly two millennia written testimonies also suggested that 'endemic plague' existed, causing malignant lymphatic swellings but less dramatic mortality crises. The novel scientific work that best accounted for plague outside urban centers, first coalesced during the 1920s, in research conducted for the League of Nations' health division, the *Office International d'Hygiène Publique*. Portuguese delegate Ricardo Jorge during the 1920s headed a commission that synthesized evidence for *Y. pestis* in mammals other than commensal rodents, spread by fleas other than *X. cheopis*. Jorge himself had long experience managing plague. Vilified for his aggressive plague containment measures in Porto, 1899, he later became Portugal's inspector general of public health, having to confront why plague was difficult to eradicate in Madeira and the Azores, islands vital to Portugal's economy. Jorge offered the term *peste silvatique* [sylvatic plague] to characterize plague maintained in regional *foyers* (or enzootic foci), in a wide array of non-urban rodents and lagomorphs that transmitted plague year to year through a wide variety of fleas. But he and all the contributors to the plague commission of the League of Nations believed that only *R. rattus* infection propagated plague pandemics. Russian investigators became leaders in this field of plague studies. In the 1920s older Tsarist anti-plague institutes and field stations were still struggling after the Revolution, but the USSR over the following decades would steadily expand the mission and reach of plague research, producing many leaders and training programs in the study of endemic, or wild plague. E.N. Pavlovsky's model of plague 'focality', studying naturally endemic plague zones with attention to ecological and environmental drivers of plague outbreaks dominated ongoing plague control approaches after the end of the Second World War.

For English-speaking audiences some dedicated plague investigators of the interwar period, Robert Pollitzer, Wu Liande, Karl F. Meyer, and L. Fabian Hirst, ventured historical reflections on plague history that paired reflections on remote sporadic plague outbreaks alongside the dominant narrative of great historical plague pandemics. All argued that endemic rodent plague existed in Eurasia and Central Africa from 'time immemorial', thus history might be able to identify what kept plague within these 'uncivilized' areas, and what fostered its escape and expansion outside plague endemic 'foci'. Pollitzer speculated that there were physical, geographical barriers and 'sterile zones' separating endemic plague from populous regions. Pandemics occurred following human innovations in long distance trade and travel. Wu argued that peoples who had long lived in plague enzootic zones developed cultural and religious practices that helped them to avoid or contain human plague infections; unwary intruders stirred and spread infection abroad. Wu attributed much of the enormous urban mortality of great historical plagues to pneumonic plague. Meyer, the leading figure in the ecology of sylvatic plague in the western United States, from 1934 until the 1950s emphasized that most wild rodents were susceptible to plague, and that the particular characteristics of surrounding landscapes determined the extent and severity of colony infections. His eclectic historical work instead focused on European quarantine and disinfection of mail and commodities in stopping the spread of plague, an implicit argument for plague's steady disappearance from Europe. Hirst devoted far more attention to the independent agency of fleas and rodents in spreading plague, singling out historical evidence that spoke to environmental corruption as stoking plague outbreaks. Attributing importance to ubiquitous human fleas and squalid environments for the great mortality in urban plague, Hirst devoted considerable attention to progressive European ideas and the men who debated the control of plague and other epidemic diseases during the 16th through 19th centuries, emphasizing wherever possible a contrast with non-western societies.

As the international character of plague science generated new historical ideas and evidence about plague as scientific questions, practices and methods converged. Work at France's far-flung Pasteur Institutes during the 1940s through 1970s documented the passive movement of infected animals and/or their fleas, particularly along transports that brought grain to cities to explain recurring smaller-scale urban epidemics, but the temptation to reinforce the grander plague story was considerable. In 1951, René Devignat, a French bacteriologist working near Lake Albert in the Belgian Congo (now Democratic Republic of the Congo), aligned the three great multicentury waves of plague in history to three biochemically variant strains of *Y. pestis*. Believing that the first recorded pandemic of the 540s ce, originated somewhere in equatorial Africa, Devignat labeled his modern central African isolate *antiqua*. He then ventured that medieval and early modern European plagues, from the Black Death (1347–53) until the horrific 1720–22 plague of Marseille, were caused by biovar *mediaevalis* originating in the central Eurasian steppes. Devignat used biochemically distinctive isolates that Soviet investigators had collected and analyzed from Ukraine and the southern Caucasus region, but he did not borrow their views of the Eurasian origins of plague, nor their concept of 'focality'. Devignat's historical model made plagues erupting in southeastern Eurasia during the 1890s part of a 'modern' third pandemic wave attributed to a biovar *orientalis*. The third pandemic biovar supposedly originated in the Yunnan highlands of southwestern China.

This Soviet system of anti-plague research and surveillance stations ringing the USSR was by this time elaborate, their institutions comparable in geographical reach and sophistication to the French and British colonial stations. Russian investigators agreed with conclusions that Wu Liande and Robert Pollitzer offered: plague originated in central Eurasia, reaching eastern Africa at some later point in time, and this work supported an idea of the 'telluric' (in the soil) persistence of plague. The USSR's southern provinces spanned a broad region plague where outbreaks were observed continuously from the 1870s to his own time, so the idea that the Second Pandemic had ever ended was an inherently problematic historical claim. For Hirst biochemical differences in the bacillus reflected races, and lack of immunological immunity among hosts explained why plagues were uniquely devastating in Europe. Russian investigators believed instead in a broader evolutionary view, that variation and divergence among plague strains was caused by the pathogen's adaptation to new host and vector species, thus reflected how plague had survived in different geographical/ecological regions.

As a simple, elegant generalization about plague's past, Devignat's claim that the pathogen itself supplied useful historical evidence proved irresistible to historians and scientists alike. Reference to one or more of these classic three pandemics typically opens even recent scientific work on plague, even when the specific results better support a multi-local ecological model of plague

hotspots. Influential historians writing in the 1970s and 1980s borrowed from plague science to argue that infectious disease experience determined larger historical patterns and outcomes. Most historians investigated the social, political, demographic, or intellectual impacts of one or more discrete epidemics in a given locality, but two scholars offered highly influential books integrating biologists' views of plague into world history: William H. McNeill in *Plagues and Peoples*; and physician Jean-Noël Biraben, in *Les Hommes et la peste*. Biraben's masterwork has never been translated into English, but remains a staple for historical demography and epidemiology. McNeill, prominent in the field of world history, used Pollitzer's ideas of barrier zones and regionally shared infectious disease experience to make an argument why western Europeans came to dominate world events during the last 500 years. The plague-related aspects of his history drew upon triumphant public health histories such as C.E.A. Winslow's *Conquest of Epidemic Disease* (1943), Hirst's *The Conquest of Plague* (1953), and George Rosen's *A History of Public Health* (1958). Meanwhile newer trends in plague science and newer plague history increasingly diverged.

Historical Study of Plague in the Past: 1970s–2000

During the later 20th century historians with many different areas of expertise—temporal, geographical, methodological, and theoretical—challenged aspects of the science-driven history of plague. In general new historical research moved away from multicentury and multi-millennial timescales, seeking to analyze the causes and consequences of epidemic disease outbreaks within specific historical settings, and over much narrower temporal intervals. A keen awareness of our patchy understanding of earlier mortality crises initially led historical demographers to quantify and compare patterns of births and deaths, culling evidence from non-narrative archival sources. While the overall magnitude and extent of the initial Justinianic plague mortality is not quite calculable, sustained attention to the demographic impacts of the Black Death epidemic and a few of its aftershocks provides sobering confirmation that many millions died in fewer than two decades. Population decline continued for over a century. There was no common European demographic response to recurrent plagues to account for long-term demographic and economic shifts. Close study of different outbreaks showed that plague's unique and specific effects were regionally heterogeneous and everywhere difficult to characterize in their lasting historical impacts. Aggregated and diverse data streams led some to tackle a longstanding question usually assumed in earlier science-driven histories: did plague play an important role in shaping the rise of Western global dominance? Or, with plague's retreat, did the decline of recurring outbreaks in the 18th century somehow fuel the beginning phases of the modern rise of human population numbers? In the quantitative historical subfields investigators took a long multicentury perspective. Those interested in the short to medium term causes and effects of plague also disproportionately studied the second pandemic. Here, too, European archival documents permitted both in depth analysis of the political and ideological views of those in control, and some evidence the experiences and views of persons and places previously invisible within earlier plague histories.

Examining epidemics at the regional or local scale, later 20th century historians upended many of the broad historical generalizations about plague that had gone unchallenged for nearly a century. Neither the murderous plagues of late antiquity or the extraordinary Black Death epidemic of the mid-14th century independently altered the course of human history. At a middle temporal range, from decades to a century, or at a multi-regional spatial level, the supposed history-shaping influence of plague becomes equivocal. Plagues more usually resembled wars in causing temporary social and political crises, disruptions in trade and production. Despite its reputation as an indiscriminate killer, plague typically spared most of community leaders, leading to continuity of political and social power across plague events.

Urban authorities invented an array of discrete responses to the threat of plague—quarantine, the isolation of plague victims in specialized hospitals, trade and travel bans, and the disinfection of infected human locations or belongings through fire or chemicals—all of which once anchored a progressive story of plague as the 'great teacher' in the history of epidemics. Otherwise, plague did not alter European or world history to the same extent that other events may have done. In textbooks the second pandemic overlapped changes credited with a far greater role in human history: the Italian Renaissance, Protestant Reformation, print culture, overseas exploration and colonization, the rise of nation states with standing armies, early guns, early industrialization—a list that could go on. Even in many histories of medicine and science before the 1850s, theoretical discussions of plague causes or transmission had no comparable significance to the Scientific Revolution. Under the historical microscope evidence about plague in the Second Pandemic mostly revealed enduring aspects of power and poverty, modes of governance, the slow secularization of European society, and the importance of religion and art in mitigating fear.

Relatively few written documents survive from the first pandemic. Thus decades earlier than did historians of later eras ancient historians stressed the importance of identifying plague impacts across and beyond the Mediterranean littoral, incorporating wherever possible archaeological evidence about settlement decline and trade patterns. A longer-term, spatially broader understanding of intervals of crisis mortality became obligatory to understanding the decline of all Eurasian and North African societies. The first synthetic work to place the Justinianic plague and its recurrences appeared in 2007, a collection edited by Lester Little, *Plague and the End of Antiquity*. As with general European histories that explained how and when Europeans came to dominate global economies, general histories of classical antiquity and the 'fall' of Rome prior to this volume accorded plague minimal importance in shaping world history from the 500s to c. 1000 ce. This particular book's contributors engaged the complexities of making a multi-century, multi-local historical assessment of plague's impact, and greatly enlarged the geographic compass and interdisciplinary foundations of older first pandemic studies. No collection could at that point, a decade ago, include any coverage of contemporary events in South or Eastern Eurasia, or offer new evidence about plague in sub Saharan Africa or the Arabian peninsula

because written sources from these regions are exceedingly rare before the Islamic era. But the collection marked the beginning of the recent historical trend that promotes longer-term multidisciplinary, collaborative global history.

With far more written evidence available to those who study 19th and early 20th century plague than is available to second pandemic historians, the social and ideological contexts in which plague decisions and observations were made can be examined in detail, and be compared with equivalent evidence from place to place. The inquiries reveal that modern-seeming statistics are nonetheless problematic as data. In other words, clinical and epidemiological evidence from the third pandemic urban outbreaks needs to be understood as historical, not contemporary, testimonials of plague. Early 20th-century conclusions about the vulnerabilities or dangers of plague are inseparable from their prejudices concerning race and class aspects of victimization, providing ample reason to doubt some of their findings. For example, very high case fatality rates occurred among hospitalized or otherwise isolated plague victims in Asian cities controlled by European colonial administrators. The recorded deaths almost exclusively occurred among those of non-European origins, but few of these patient diagnoses were confirmed by laboratory isolation of the plague pathogen. Two important and distinctive historical features of this pandemic for its historians are instead the scientists' adoption of maps as a fundamental analytical tool for understanding plague spread over time and space, and the use of photography to convey observations not easily mapped or tabularized. Interestingly there are very few known photographs of the pathognomonic indicator of acute bubonic plague, the bubo, but we have many cityscape images of urban slums. Cameras documented the supposed danger zones within cities and the often-uniformed authorities who dealt with the less biologically specific fear that plague provoked.

The belief that early 20th century plague publications can inform us about first and second pandemic outbreaks may also require review as the global history of plague is rewritten. At the opening of the present century two respected medieval historians offered strikingly different, conflicting histories of the Black Death, in books that are widely cited and consulted among plague scientists. Both scholars are fully confident in the factual reliability of scientific observations on plague made in the opening decades of the third pandemic. Ole Jørgen Benedictow assembled historical studies and evidence about the initial pandemic wave as few others could do; his linguistic command exceeds that of most solitary investigators. Benedictow described the Black Death's spread across Europe, guiding his historical research with detailed knowledge of the work of British investigators in Mumbai a century earlier. He assumed that *Rattus rattus* and *Xenopsylla cheopis* were widely prevalent in Western Europe during the medieval centuries, and that plague spread in 'metastatic' fashion through the passive transport of these hosts along lines of human communication, leaping over rural areas to reach the next populous settlements. Samuel K. Cohn, Jr., instead pored over the clinical and epidemiological reports of British investigators in India, finding few salient resemblances between their descriptions of plague and eyewitness or medical accounts of the 14th-century disease. Cohn's work effectively translated many historians' doubts about our ability to trust disease diagnoses made with pre-modern medical or cultural perspective. Arguing that the word 'plague' in the past never signified an infection caused by a specific microorganism, Cohn was addressing a dominant perspective in the cultural history of medicine since the 1990s, that the early germ theory era in scientific thinking created an epistemological break with our collective understanding of written historical sources. But Cohn went much further, arguing that late medieval records convincingly revealed that modern bubonic plague never existed in Western Europe. After 2010, it was no longer possible to support his skepticism about either the first or second plague pandemic.

New Plague History From New Plague Science: Archaeogenomics

In 2010 a team of genetic and molecular archaeological investigators reported finding fragments of ancient *Y. pestis* DNA in a few individuals who died in London during the Black Death. The rapid technological innovations that led to the important 2010 publications. Bos and colleagues were assisted by historical documentation affirming that the East Smithfield cemetery was used only during this first epidemic of the Second Pandemic. Collaboration with professional historians and archivists matters to current scientific research on past plagues. Another international team (Morelli and colleagues) offered the first complete phylogeny of *Y. pestis*, plague's global family tree on which the London evidence could be located. These two publications ended a tense and highly competitive decade during which the drama of plague took place in laboratories around the globe and involved investigators with markedly different disciplinary skills and institutional settings. In a now-classic 2011 article, historian Lester Little summarized the frantic, not always civil competition to retrieve *Y. pestis* aDNA from first and second pandemic victims. The technological changes to our ability to know about the evolution of major human pathogens is a part of the recent history that did not principally concern Little, who considered instead how plague science demanded historical attention to examine large questions at global or continental scale, and over much longer temporal intervals. Despite massive attention to the cultural, social, intellectual and economic issues of plagues past, the new scientific studies exposed the relative lack of historical attention to climate, environment, human interactions with possible hosts and vectors, living conditions, and activities along pathways of human trade, travel and communication (rather than a selective focus on the nodes and endpoints of such exchanges).

The 2010 breakthroughs built upon specific archaeogenomic advances, 1996–2006. Since the late 1990s, genetic analysis of the evolution of *Y. pestis* placed its geographical origins somewhere in the vast terrain of central Eurasia, confirming the earlier conclusions of both Chinese and Soviet plague scientists. In 1998 Marseille-based investigators, Michel Drancourt and Didier Raoult, isolated ancient *Y. pestis* DNA from individuals buried during the 1720–22 plague. They reasoned that aDNA bacterial fragments could survive in dental pulp, because the end stage of most mammalian plague infection involves blood-borne dissemination of the pathogen. Dental pulp did not decay along with other soft tissue, being lodged in an area of the skeletal

remains that was not exposed to soil contamination. Raoult and Drancourt used PCR (polymerase chain reaction) techniques to amplify fragments of bacterial aDNA, and isolated fragments of one distinctive *Y. pestis* plasmid, thus showing the presence of *pestis* rather than the ubiquitous and mostly benign precursor, *Y. pseudotuberculosis*. Accused of reporting results that reflected laboratory contamination, the Marseille team and the archaeologists working with them refined and revised their methods, with which an entirely different group of Munich researchers vindicated the primary claim by isolating *Y. pestis* aDNA from humans buried during the Justinianic plague era. Two different technical innovations of the early 2000s, “next generation sequencing” of aDNA and the development of a rapid field test for DNA associated with one of the virulence-conferring plasmids of *Y. pestis* (developed by Pasteur Institute plague control teams in Madagascar around 2004), increased confidence in the isolation of *Y. pestis* from human skeletal remains.

In other pioneering work in the late 1990s, Mark Achtman and colleagues showed that *Y. pestis* was a recent emergent pathogen at most a few thousand years old. This line of historical-scientific investigation led to the breakthrough work of Yujun Cui and colleagues in 2013, identifying the approximate time and broad geographical location where the medieval plague pandemic likely emerge: a polytomy, described by popular terms such as a “big bang” event. Their complex research is accessible to a non-specialist audience by medievalist Monica Green. We know that all known pathogenic strains of *Y. pestis* emerged in somewhere in central Eurasia, from an ancestral strain of soil dwelling microorganism, *Y. pseudotuberculosis*. The new species has three plasmids, two of which confer the ability to replicate in fleas and survive in mammals, genetic changes that made *Y. pestis* an extraordinary human pathogen. Knowing something of plague archaeogenomics will lead historians and archaeologists to new research on multi-millennial human-driven changes to landscapes and use of natural resources.

Nothing in the new genomic history of plague has as yet either confirmed or refuted the older historical construction of three pandemics. Historian Robert Hymes used Chinese sources and the new genetic findings to identify catastrophic epidemics in the Qinghai/Tibet plateau, perhaps a century before the Black Death reached Europe. Otherwise the question of plague’s origins brings newly unsettled historical issues to the foreground, and it exposes the inadequacy of any global history of plague written solely from Western historical evidence or perspective. 20th-century research on plague ecology was not incorporated into earlier historical work that addressed one or all of the three pandemics. A prominent medieval economic historian, Bruce Campbell very recently identified the environmental and climatological changes across the Northern Hemisphere that could explain the Central Asia *Y. pestis* polytomy of the 1200s ce. Campbell aggregated human-generated documentation from European archival sources, looking to commodity prices, the volume of trade across Eurasia and North Africa, and work on demographic and settlement patterns across the 13th through 16th centuries. He then temporally aligned various historical climatological measures of regional precipitation and aridity to the historical evidence. More work of this sort is underway with investigations on the first pandemic.

Secondly, historians’ study of the third pandemic outbreaks once reflected professional interest in processes related to modern globalization. Ongoing research on this pandemic exposes the near absence of in-depth historical analysis of plague in regions outside Europe and the Mediterranean littoral, for either of the earlier pandemics. In other words, plague history is finally becoming an important historical topic within global history. Demand for a more inclusive, expansive understanding of the past arose independently among professional historians, while the archaeogenomic revolution was underway. Varlık’s very recent study of plague in the early Ottoman empire, from the Black Death to the late 16th century, uses largely untapped Ottoman archives to undermine assumptions about the role of Anatolia and the Levant as regions that repeatedly seeded plague outbreaks in Western Europe. Plague in Anatolia instead expanded as Ottoman contacts with Venice and other western port cities increased; plague became endemic within Ottoman lands after, not before, the Black Death, through the physical infrastructure that a powerful, centralizing state built to connect governors to the governed.

Specialization and collaboration across disciplinary divides is a promising approach to next-generation plague history. A subset of exceptionally well educated, western-trained plague investigators a century ago could once devote free time to doing plague history. Even then important scientific research from Soviet scientists mid-century and Chinese investigators in later decades, uncovered important evidence that was not easily integrated with settled history. We now need a global framework for investigating multicentury, multiregional phenomena. The half-century’s work spent dismantling some of old assumptions about plague in human history has created a more confident and informed generation of historians, discontent with static re-presentations of early science-driven history. As in the scientific community, new studies in history must be cast and argued simultaneously at local and global scale. Re-understanding the environmental drivers of catastrophic plague outbreaks should engage historians and the scientific community alike, for historical sources document the destructive potential and extraordinary virulence of pre-modern plague crises, causing losses nearly unimaginable today. A broader and multidisciplinary approach to historical plagues becomes necessary to understand whether human activities were related to the pathogen’s emergence, spread, and variable factors governing persistence.

Glossary

case-fatality rate The number resulting from dividing the total number of cases caused by a disease by the total number of deaths of the disease.

inoculation (sometimes called 'variola') The introduction of pustular or scab material containing variola virus, the causative agent of smallpox, into the skin. This usually induced a localized infection that protected against natural smallpox but sometimes proved fatal.

poxviruses Members of a large family of viruses, each of which tends to be specific to a particular species (e.g., canarypox, mousepox, and raccoonpox). Only four are known to infect humans: variola, vaccinia, cowpox, and monkeypox.

vaccination The introduction of pustular or scab material containing vaccinia or cowpox virus into the skin.

variola The word is used almost interchangeably with 'smallpox'. It is derived from the Latin word 'pock' or 'pustule'. The term 'great pox' was used to describe syphilis, the lesions of which are much larger.

WHO World Health Organization

Defining Statement

The history and nature of smallpox is summarized beginning in earliest historic times. A devastating disease, it remained uncontrolled until the discovery of a vaccine in the eighteenth century. Disease control was superseded by a global program of eradication which resulted in the last cases occurring in 1977. The smallpox virus now remains in only two research laboratories (U.S., Russia) under high biosecurity conditions overseen by WHO scientists.

Introduction

Throughout history, until its eradication in 1980, smallpox was the most serious and feared of all the pestilential diseases with a history dating back to the time of the Pharaohs. It was a disease caused by the variola virus, which infected only humans. All countries with no regard to climate once experienced the disease. The severe form of smallpox, variola major, killed some 30% of its victims, but among the unusually susceptible Amerindian populations, case-fatality rates as great as 60–80% were recorded. There was no treatment for this disease. Smallpox was transmitted directly from person to person. Those who recovered from the disease were immune from acquiring a second infection. The disease was marked by high fever and the development of a characteristic pustular rash. As the disease progressed, scabs formed over the pustules and eventually separated leaving permanent, deeply pitted scars, which were most prevalent over the face. Some victims were permanently blinded. Of all the infectious diseases, none had the capacity both to spread so widely and to inflict such a high mortality as did smallpox.

In the eighteenth century England, it was widely recognized that milkmaids, in particular, seldom acquired smallpox and some attributed this to their having experienced a pustular infection of their hands resulting from contact with pustules on cows. As we now know, these infections were caused by the cowpox virus, which is closely related to variola. In 1796, Edward Jenner, a physician, demonstrated that this pustular material could be deliberately transferred from person to person by inoculation into the skin. He showed that individuals so treated were protected from acquiring smallpox when they were later challenged. This was the world's first vaccine and its discovery is acknowledged as one of the most important in the history of medicine.

As vaccine use increased and more potent and heat-stable vaccines became available, smallpox steadily receded until, in 1967, with only 31 countries still infected, the World Health Organization (WHO) launched a global campaign to eradicate the disease. This proved to be a success. The last naturally occurring case was a Somali resident who became ill on 26 October 1977. In 1980, smallpox was declared to have been eradicated and vaccination ceased everywhere. Except for some workers in orthopox virus laboratories.

[☆]*Change History:* August 2014. DA Henderson has updated the text and further reading.

This article is a reprint of D.A. Henderson, *Historical Smallpox*, *Reference Module in Biomedical Sciences*, Elsevier, 2014.

History

Smallpox was an ancient disease and affected specifically humans. Those who became ill could transmit infection only during the 2 to 3-week period of acute illness; second attacks of smallpox were rare. For the virus to survive, it was necessary for it to infect one person after another in a continuing chain of transmission. Thus, to sustain the chain of infection, a moderately large population in reasonably close contact with each other was required. For these reasons, it is assumed that the disease must have arisen less than 10 000 years ago, a time when agricultural settlements were initially developing. Three Egyptian mummies from the 18th to 20th dynasties (1570–1100 BC), apparent victims of the disease, all show the characteristic pustules of acute smallpox.

The subsequent spread of smallpox is difficult to trace because of the paucity of historical records that describe disease symptoms and epidemics in sufficient detail to identify them. Accounts of the disease in India suggest its existence there for almost as long a period as in Egypt. From India, it appears to have spread across China (about 250 BC) and to other parts of Asia. Periodic outbreaks occurred in Europe but not until the eighth century did smallpox become firmly established throughout the continent. By the seventeenth century, smallpox killed more than 400 000 people in Europe every year.

The saga of smallpox in the Americas represents one of the most catastrophic, yet little known chapters in the history of mankind's struggle against disease. In 1507, soon after contact with the New World, the Spaniards brought smallpox to Hispaniola. By 1541, the island's population, estimated to have originally been between 300 000 and 1 000 000 persons, numbered only 500. Several diseases contributed to this disaster but smallpox was the main offender. In 1520, Cortes, with an army of 500, was sent to Mexico to capture additional slaves. Smallpox traveled with him and soon spread throughout Mexico and Middle America and eventually into the vast Incan Empire of the Andean Region. By the end of the sixteenth century, populations throughout Central and South America were estimated to have decreased by 80–90%. North American Indians fared no better.

In all parts of the world, smallpox was known and feared. Special deities were found among populations in many parts of Asia and Africa. However, in India, sometime early in the Christian era, an unusual practice was discovered which served to protect against fatal smallpox. It was called inoculation. Pustular or scab material was taken from a smallpox lesion and inoculated into the skin of a susceptible person. Smallpox infection induced in this manner rather than by the usual route of inhalation, usually resulted in a much less serious disease. Customarily, the recipient would experience fever and malaise and after 5–7 days would develop a pustular lesion at the inoculation site. Most persons recovered uneventfully and were thereafter immune to acquiring smallpox. However, the inoculated individual could transmit infection to others and, in some, a more severe illness occurred which was sometimes fatal.

The practice of inoculation spread to China and Southwest Asia although it is uncertain as to what proportion were so treated. In 1721, the practice was introduced into England and later into other parts of Europe as well as North America. Although it was accepted in some areas, the practice was not enthusiastically embraced everywhere, in part because of the sometimes fatal outcomes and in part because of the occurrence of new smallpox outbreaks developing as a result of spread of the virus from inoculees.

The concept of inoculation as a protective measure effectively established this technique as a common practice. Thus, Edward Jenner utilized a form of inoculation in his now famous experiment in which he took pustular material from a cowpox lesion on the hand of a dairymaid and inserted it into the arm of a young boy, James Phipps. The use of cowpox was suggested by local lore, which held that dairymaids did not acquire smallpox because of having had a cowpox infection. Jenner attempted to inoculate Phipps after some weeks with pustular material from a smallpox lesion and demonstrated that he could not be infected. He published this and other observations in 1798 and soon thereafter the cowpox vaccine (an orthopoxvirus, like smallpox) was shipped to countries around the world. Jenner's discovery was acclaimed at the time and is recognized even now as one of the most important of all medical discoveries.

However successful vaccination, its widespread application proved difficult. Until late in the nineteenth century, vaccination was conducted by the arm-to-arm transfer of the vaccine material. When a vaccination was unsuccessful and no other material was available, fresh material had to be obtained. Cowpox, however, was found only in Europe and occurred only sporadically. The reason for this, as we now know, is that the natural reservoir of cowpox is actually small rodents. Thus, although the virus was continuing to circulate, cows themselves only occasionally acquired infection from the rodents but this was not known at the time. When efforts were made to ship new material, it often would deteriorate en route. Eventually, it was discovered that syphilis and hepatitis B could also be transferred by inoculation. Incidents occurred, in fact, in which cutaneous lesions of syphilis were thought to be vaccinia pustules and large-scale syphilis outbreaks resulted when the pustular material was transferred.

Late in the nineteenth century, cowpox began to be grown on the scarified flank of a calf or sheep, thus assuring a more reliable and ample supply of vaccine. In the 1920s, French and Dutch scientists showed that a dried preparation could be produced which was stable at ambient tropical temperatures. However, methods for drying the vaccine frequently resulted in a final product that was heavily contaminated with bacteria. Finally, a commercial process for freeze-drying the vaccine, perfected in England in the early 1950s, opened the way for widespread vaccination throughout the world and eventually for the global eradication program. Beginning in 2002, the vaccine began to be grown in tissue cell culture.

Smallpox, The Disease

Etiology

The causative agent of smallpox, variola virus, belongs to the genus *Orthopoxvirus*, subfamily *Chordopoxvirinae*, family *Poxviridae*. Three other members of this genus can also infect humans: monkeypox, cowpox, and vaccinia. However, none of the three are readily transmitted from person to person. The poxviruses are the largest and the most complex of all viruses. The virion is a

brick-shaped structure with a diameter of about 200 nm. Its lipoprotein outer membrane (envelope) encloses a single linear, double-stranded DNA. Replication of the poxviruses occurs in the cytoplasm. Unlike other DNA viruses, the poxviruses encode the dozens of enzymes required for transcription and replication of the viral genome. The viral core is released into the cytoplasm after fusion of the virion with the plasma membrane. Restriction endonuclease maps of the genome definitively identify the species of the *Orthopoxvirus* genus.

Pathogenesis

Two distinct forms of smallpox have been observed over the years: variola major with a case-fatality rate of 20–30% and variola minor with a case-fatality rate of 1% or less. Variola major appears to have predominated throughout the world at least through the nineteenth century. A much less virulent form of the disease, usually called variola minor or alastrim, was first definitively identified in South Africa toward the end of the nineteenth century. The rash of variola major is indistinguishable from that of variola minor. This form of smallpox may have been present in some areas of the world before this time but few records are available which set forth numbers both of cases and deaths along with a reasonable description of the disease. Variola minor appeared in the United States at the beginning of the twentieth century and spread rapidly across the country eventually displacing variola major. From the United States, variola minor spread to Latin America and to Britain.

Throughout Asia, variola major was the only type of smallpox seen, whereas in Africa, other variants of variola major occurred resulting in case-fatality rates of between 10 and 15%. Although epidemics of variola minor with the very low case-fatality rates were found in Ethiopia beginning in the mid-1970s, historical reports suggest that before this time, case-fatality rates more closely resembled those found elsewhere in Africa.

Natural infection occurred by the implantation of variola virus on respiratory mucosa. After migration to and multiplication in regional lymph nodes, viremia developed followed by multiplication of virus in the spleen, bone marrow, and lymph nodes. A secondary viremia with fever and toxemia began about the 8th day. The virus, contained in leukocytes, then localized in small blood vessels of the dermis and mucosa. This process resulted in formation of the characteristic vesicular and pustular lesions. Hemagglutinin-inhibiting (HI) and neutralizing antibodies could be detected beginning about the 6th day of illness. Neutralizing antibodies were long lasting, whereas HI antibodies declined to low levels within 5 years. Little is known about the development of cell-mediated immunity. Vaccinia-induced antibody responses developed more rapidly, accounting for the fact that complete or partial protection of individuals was possible even among those vaccinated several days after exposure. Secondary bacterial infection was not common, and death, when it occurred, probably resulted from the toxemia associated with circulating immune complexes and soluble viral antigens.

As the patient recovered, the scabs separated and the characteristic pitted scarring gradually developed. The scars were most evident over the face and resulted from the destruction of sebaceous glands followed by shrinking of granulation tissue and fibrosis.

Symptoms

After an incubation period of 7–12 days, the patient experienced a 2–5-day period of high fever, malaise, and prostration with headache and backache. Those with variola major were usually sufficiently ill to want to stay in bed. A maculopapular rash then began to develop at which time the patient first became contagious to others. The rash appeared first on the face and forearms and on the mucosa of the mouth and pharynx. It then spread to the trunk and legs. Within 1–2 days, the rash became vesicular and then pustular. The pustules were characteristically rounded, tense, and deeply embedded in the dermis. Crusts began to form about the 8th or 9th day. When they separated, they left pigment-free skin and eventually scars. The eruption was characteristically more extensive on the face and distal parts of the arms and legs, and lesions were occasionally found on the palms and soles. Although the case-fatality rate among unvaccinated victims of variola major was usually about 30%, a more severe form accompanied by extensive hemorrhage occurred in about 1 case in 20 and was invariably fatal.

Persons with variola minor usually experienced a less extensive rash and less prostration than with infection caused by variola major but the rash was indistinguishable from that of variola major. A milder form of disease was also seen among those who had previously been vaccinated, the rash in such persons tended to be more scant and atypical and the evolution of lesions more rapid.

Supportive therapy, maintenance of fluids and nutrition, and good nursing care were the best that could be offered to most patients. On the infrequent occasions when bacterial infections supervened, antibiotics were appropriate. Antiviral drugs, most notably methisazone and the arabinosides, were reported in some early studies to be effective in early treatment or prophylaxis, but confirmatory studies showed otherwise.

Laboratory Diagnosis

Diagnosis of a poxvirus infection is confirmed rapidly by electron microscopic identification of virus particles in vesicular or pustular fluid or scabs. All orthopoxvirus virions have the same appearance. The four orthopoxviruses, which infect humans, grow and produce a cytoplasmic effect in cultured cells derived from many species but they cannot usually be differentiated from each other in most preparations. For diagnostic purposes, PCR techniques are now widely available which readily identify the different orthopoxvirus species, each of which has a distinctive DNA map.

The Global Eradication Campaign

A global campaign for the eradication of smallpox was proposed by the Soviet Union in 1958 and agreed by the World Health Assembly. However, over the succeeding 8 years, little progress was made. At the time, WHO and many of the smallpox-endemic countries were fully preoccupied with a global malaria eradication program which had begun in 1955 and which consumed a substantial proportion of the WHO's budget, personnel, and time. As the years passed, many began to express skepticism that malaria or, for that matter, any disease could actually be eradicated.

Soviet Union delegates, joined by others, expressed increasing displeasure that the WHO did not assign a higher priority to the smallpox effort, and demanded finally that steps be taken to work out a definitive plan and cost estimates for an intensified program. Meanwhile, in recognition of International Cooperation Year, the United States, in November 1965, announced its intention to provide support to 18 countries of Western and Central Africa in an effort to eradicate smallpox and control measles. At the 1966 World Health Assembly, the United States joined the Soviet Union in arguing for the development of a greatly intensified global eradication campaign. Some countries, as well as the Director General of WHO, opposed the concept of smallpox eradication as being technically impossible; others objected to increasing the WHO budget by \$2.5 million per year to provide a portion of the needed financial support for the effort. Eventually, by the margin of only two votes, the decision was taken to intensify the eradication effort. Assembly delegates proposed a 10-year target.

In 1967, the year the program began, 46 countries reported smallpox of which 31 were considered to have endemic disease while 15 recorded imported cases. Estimates later showed that some 10–15 million cases and 2 million deaths occurred the same year.

The basic strategy for the program was twofold: population-wide vaccination and a surveillance-containment program. These were to be initiated simultaneously at the outset of each program. The vaccination program was intended to reach 80% of the population in each of the endemic countries and in neighboring countries at risk of imported cases. Those directing the program reasoned that a substantial level of vaccination immunity would sufficiently diminish the rapidity of virus spread so as to permit the surveillance-containment program to be fully effective. The latter program required that a reporting system be developed such that each hospital and health center would report each week as to the number of smallpox cases diagnosed. When cases were reported, a surveillance team would go to the field, seek to find other cases, and vaccinate household and village contacts in hopes of stopping the chain of transmission of infection.

The strategy of surveillance and containment was soon discovered to be far more effective than was expected based on the conventional wisdom of the time which held that smallpox spread rapidly and widely. Through field epidemiology, it soon became clear that a given patient seldom infected more than two to five others, usually household members or close friends and they normally did not develop illness until 7–12 days after exposure. Thus, smallpox usually spread comparatively slowly and cases tended to cluster within cities and within geographic areas. This greatly facilitated the containment activities.

Many observations of importance gradually shaped the program. It was found that with good planning and involvement of community resources, vaccinators could regularly average 500 or more vaccinations per day and vaccination coverage of more than 90% was to be expected. In contrast, vaccination coverage that relied solely on clinics and hospitals for dispensing vaccine seldom exceeded 60%.

Quality control was essential. To assure performance in vaccination, independent assessment teams checked a sample of villages vaccinated by the mass vaccination teams to assure that both coverage and vaccine efficacy standards were met. Where they were not, the entire area was revaccinated. The supply of vaccine was a special problem. As the program began, it was discovered that not more than 10% of the vaccine then in routine use met accepted international standards. Smallpox vaccine was then being produced in more than 40 different laboratories scattered throughout the world. Few undertook to perform routine quality controls of their product. Given the fact that the WHO allocation for smallpox eradication was too meager to purchase required vaccine from established laboratories, the decision was made to foster improvement in vaccine quality in the existing production facilities. Two laboratories, one in the Netherlands and the other in Canada, undertook to perform independent testing for all vaccine to be used in the program. WHO convened a panel of expert consultants from the major production laboratories to develop a standard manual of procedures. Many consultants then traveled to the various laboratories for purposes of training and evaluation. Remarkably, within 4 years, all vaccine met international requirements and more than 80% of the vaccine was able to be produced in the endemic countries themselves.

Research made important contributions. A new method for vaccination resulted in more successful vaccinations utilizing much less vaccine. In 1967, a new vaccination needle (the so-called bifurcated needle) was in the late experimental stages at Wyeth Laboratories in the United States. With Wyeth approval, WHO undertook additional studies with the needle, altered the technique for its use so that it was given by multiple punctures, and introduced its use worldwide. Using the needle, only one-fourth as much vaccine was required as was needed using the standard techniques. Training of vaccinators could be done within a matter of minutes and the result was a higher proportion of successful takes. The needles were fabricated from stainless steel and could be boiled and reused many times.

A second important finding derived from field epidemiological studies, which revealed that the protection afforded by primary vaccination was not the 3–5 years that most textbooks asserted but, rather, showed a 90% efficacy rate at 20 years. With this discovery, it was possible to focus efforts on assuring that every person had a vaccination scar rather than assuring that everyone had been vaccinated within the preceding few years.

Rapid progress was made in the campaign so that by 1973, smallpox was largely confined to four countries of South Asia and, in Africa, to Ethiopia. However, in Asia, efforts such as had been successful in the Americas and in Africa proved far less efficacious. The problem was that with a more extensive infrastructure for road and rail travel in India and Pakistan, people traveled frequently and

over considerable distances, often returning as a family to a home village when one of the families became ill. The result was that smallpox spread more rapidly than in other countries and over longer distances. In the summer of 1973, it was decided with Indian Government authorities to assign large numbers of health personnel to undertake a 10-day search throughout all the villages, towns, and cities of the country. It was hoped that this would permit cases to be found much earlier so that surveillance teams could move rapidly to vaccinate household and village contacts and so prevent further spread of the disease. The first search found tens of thousands of previously unreported cases, many more than had been expected, but early containment was then possible. Every few months the searches were repeated with increasing precision, eventually reaching every household in every village in India. Less than 2 years elapsed before India and all of Asia became smallpox-free.

As the numbers of cases decreased, it became the policy to offer a small reward to anyone reporting a case that proved to be smallpox. As the cases became fewer, the reward was increased so that by the end of the program, a reward of \$1000 was being offered for the report of a case that could be confirmed as smallpox. This technique proved to be exceedingly valuable in the closing phases of the program in which each country had to demonstrate to an independent commission that it had a surveillance network that had been functioning effectively for at least 2 years after an endemic area was free of smallpox and that surveillance was sufficiently sensitive to detect cases if present.

The last naturally occurring case of smallpox occurred on 26 October 1977 in Somalia, albeit two further cases occurred, both in Birmingham, England, in 1978, as the result of a laboratory accident. As smallpox incidence declined, an independent international commission was created to review the work of the individual national commissions and to define additional studies and data that it required to assure itself that eradication had been achieved. The Committee last met in December 1979 and, at that time, pronounced that it was satisfied that eradication had been achieved. The Chairman of the Committee reported its findings to the Director General and the World Health Assembly in May 1980. The Assembly, in a specially convened session, passed a resolution indicating that eradication had been achieved and recommended that all countries cease vaccination.

Posteradication

A Possible Natural Reservoir of Variola Virus

From the inception of the program, eradication program staff had been concerned about the possibility, however remote it may have seemed, that there might be an unsuspected natural reservoir of smallpox. Not to be forgotten was the fact that a yellow fever eradication program had to be abandoned in 1932 when it was discovered that there was an unsuspected jungle reservoir. Thus, special efforts were made throughout the course of the eradication program to identify the source of all smallpox cases that were reported from countries that were believed to be free of the disease. It was believed that, if there were a natural reservoir of some sort or if it were possible for people to be infected from scabs or other material still remaining in the environment, smallpox cases would be found for whom the source of infection was not apparent. No cases of this type were found.

Monkeypox, a Disease in Man Similar to Smallpox

Monkeypox is caused by a virus that is a member of the *Orthopoxvirus* genus and so is closely related to smallpox. In man, it resembles smallpox clinically and is associated with a case-fatality rate of 10–15%, similar to that of smallpox in central African countries. Initially, there was concern that it might adapt to spread in humans.

Human monkeypox cases were first detected in 1970 and studied intensively by WHO teams throughout the 1980s. They documented the fact that the natural monkeypox virus reservoir was actually ground squirrels and that man only infrequently became infected. However, the teams discovered that the virus could be passed from person to person although it was much less contagious than was smallpox. Moreover, the studies indicated that it was highly unlikely that the virus could continue to spread even in populations that had never been vaccinated.

During 1997–98, reports of large outbreaks of human monkeypox cases in the Democratic Republic of the Congo raised questions as to whether monkeypox might be spreading so readily from person to person as to replace smallpox as a dangerous contagious disease. The reports in 1997 of large numbers of human monkeypox cases were widely publicized and caused alarm. However, as investigations progressed, it became clear that a large proportion of the cases were chickenpox and that there was little evidence to suggest that the smallpox virus had changed its character.

Destruction of Remaining Smallpox Virus Stocks

Following the 1980 declaration of smallpox eradication, a WHO expert committee was constituted to consider additional steps which might be taken to assure confidence in the fact of eradication and to advise regarding the continuation of a vaccine stockpile among other matters. One important question was to decide whether the known remaining stocks of variola virus should be destroyed.

As a result of WHO recommendations, 74 of 76 laboratories known to have stocks of variola in 1980, had destroyed their stocks or sent them to one of two WHO reference laboratories, located, respectively, in Moscow, Russia, and in Atlanta, Georgia.

At meetings in 1986 and 1990, the expert committee affirmed the desirability of destroying the variola stocks but advised that this be deferred until virus strains could be appropriately mapped, cloned, and sequenced. By 1994, this work had been completed

and endorsements supporting the destruction of the virus strains had been obtained from five prominent scientific bodies including the International Union of Microbiological Societies, the Russian Academy of Medical Sciences, and the board of scientific counselors of the US National Center for Infectious Diseases.

At its 1996 meeting, the World Health Assembly voted to accept the recommendations of the expert committee and proposed that the virus strains at the two laboratories be destroyed in June 1999. However, at subsequent meetings of the World Health Assembly, the last in 2014, several countries argued that it was important to retain the virus so as to permit studies to be undertaken to develop a more attenuated vaccine than that which had been routinely used and to develop antiviral drugs that would be suitable for treating smallpox cases should cases recur. On each occasion that a postponement in destruction has been agreed upon by the Assembly, it has added the provision that research studies using smallpox virus must be approved in advance by a designated WHO Committee and reported to the Assembly and that each of the two laboratories be visited by WHO-appointed experts to provide independent reassurance to all member countries that adequate measures were being taken to preclude smallpox virus from being released.

The rationale for retaining the virus has continued to be viewed with skepticism by the majority of countries and many scientists who believe that the argument for virus destruction is a compelling one as it would make it less likely that the virus would be released either by accident or for malicious purposes.

Smallpox as a Terrorist Weapon

There is increasing concern that biological weapons might be deployed by terrorists either acting as a dissident group or under state sponsorship. Until the early 1990s, biological weapons had not been considered to be a threat. The primary reason was that all countries had agreed in 1975 to abide by a Biological Weapons Convention which required all countries to cease work on organisms for use as biological weapons and to destroy such stocks as they possessed. Smallpox, in any case, was considered an unlikely agent because of the high level of population immunity, the availability of a vaccine, and the knowledge that vaccination of contacts can rapidly and effectively control epidemics. Thus, vaccination programs ceased in 1980, all smallpox vaccine production stopped, and the facilities for producing vaccine were converted into other uses.

During the 1990s, it became known that the Soviet Union, ever since the Biological Weapons Convention had come into force, had been engaged in a massive research effort to develop biological weapons, to develop new mechanisms for their dispersal, and to produce them in large quantity. Such information was provided by a high-ranking defector from the program. President Yeltsin later confirmed publicly that the program had indeed existed. He took measures to close the civilian component of the program but the status of the military component is unknown. In all, more than 50,000 persons had been involved in more than 50 of the most advanced biological laboratories. Smallpox virus was considered to be among the most effective of the possible biological weapons and, of the smallpox strains, one that had been recovered in India in 1966 was considered by Russian scientists to be the most pathogenic. Special studies were undertaken to determine the possibility of developing recombinants of smallpox with Venezuelan equine encephalitis virus and with Ebola virus, and a major smallpox virus production unit was built that was capable of producing tons of smallpox virus.

Subsequent to the break-up of the Soviet Union, many of the former biological weapons laboratories have had to sharply reduce the sizes of their staffs. Some of those previously engaged have emigrated to Western countries and some are believed to have consulted and worked in laboratories in countries that are involved in fostering terrorism. It is unknown whether some or any have carried their knowledge or strains of smallpox or other agents elsewhere.

Because of these factors, smallpox vaccine production continued in at least two laboratories; a number of countries have stockpiles of vaccine; a WHO reserve stockpile is in process of being augmented; new diagnostic tests for smallpox have been developed and distributed; and special teams have been trained for immediate deployment should an outbreak be suspected. Studies are continuing to develop a new less reactogenic vaccine and anti-viral drugs. As of 2014, none proved to be fully satisfactory.

Glossary

- adaptation** Change in the ability of a microbe to utilize a specific nutrient after exposure to that nutrient.
- animalcules** Term given to microscopic organisms first described by Leeuwenhoek.
- antisepsis** Practice of using chemical agents to kill microbes during surgical or other procedures.
- asepsis** Practice of surgical or other procedures carried out in the absence of microbes.
- attenuation** Reduction in the virulence of a microbe by certain growth conditions or chemical or physical treatments.
- chemotherapy** Treatment for disease with specific drugs of known composition, usually a natural or synthetic organic compound, sometimes including the toxic, antimicrobial natural products of other organisms, termed antibiotics.
- contagion** The belief that an illness can pass from one individual to another by contact or by indirect transfer of germs.
- cyclogeny** A theory of life cycles of bacteria, usually in terms of an entire population of microbes.
- dissociation** The phenomenon by which bacteria with different properties, usually related to virulence, arise from a homogeneous population of bacteria. Now attributed to gene mutations.
- episome** An extrachromosomal genetic element in cells, which can sometimes become associated with the chromosome.
- fermentation** Classically, the process of conversion of sugar into alcohol.
- infusion** A suspension resulting from soaking or heating organic material in water, for example, tea.
- inoculation** Deliberate transfer of material from one source, such as a sick animal or a laboratory culture, into another.
- miasma** Concept of contagion by some atmospheric influences, 'bad airs', or emanations, not perceivable by the senses.
- microbe** Generic term for living organisms too small to be seen by the unaided eye.
- monomorphism** Nineteenth century doctrine that bacteria are of a fixed form or morphology and that the different forms indicate distinct bacterial species.
- mutation** An abrupt change in a bacterial character, which is stably heritable. Now known to be the result of a change in the genetic code of an organism.
- operon** A concept applied to a group of genes for functions that are regulated coordinately by means of control of the transcription, or messenger RNA synthesis, of those genes.
- plasmid** An extrachromosomal, self-replicating genetic element, which may or may not become associated with the chromosome. More general term than episome.
- pleomorphism** Nineteenth-century doctrine that bacteria are of variable form or morphology and that the different forms are not indicative of distinct bacterial species, in contrast to the concept of monomorphism.
- poisson distribution** A statistical function that predicts the probability of occurrence of all-or-none rare events, such as mutations, under the assumption that their occurrence is random.
- putrefaction** The process of breaking down, decomposition, or rotting of organic matter, similar to, but often contrasted with, fermentation.
- septicemia** A bacterial infection carried in the blood of the affected organism.
- spontaneous generation** The process whereby living organisms arise from nonliving matter. The matter may be inorganic (abiogenesis) or organic matter from previously living organisms (heterogenesis).
- transformation** A change from one form of bacteria to another, usually in a 'single property', mediated by exposure to some material, now known to be DNA, from bacteria exhibiting the second property.
- vaccine** A preparation (made in various ways) from an infectious organism that induces immunity, but not a full infection, when inoculated into a susceptible animal.
- virulence** The capacity of a specific organism to cause disease when inoculated into a susceptible host.
- vitalism** The concept that all living organisms possess a 'life force' or 'vital principle' which accounts for the distinct properties of life, beyond the chemical and physical organization of the organism.

Defining Statement

This article surveys the key landmarks in both the conceptual and the practical history of microbiology.

Introduction

The field of microbiology is defined, more or less, by the physical scale of the living objects of its study. In this sense, it began with the invention of instrumentation to visualize objects below the limits of the human eye, that is, the microscope. In another sense, however, microbiology also includes the study of properties of these objects which can be observed macroscopically or indirectly, for example, the metabolic consequences, the diseases, and the products of microbial activity. In this latter sense, the history of microbiology includes fermentations and other processing of foods, preservation of materials from microbial decay, and concepts of disease and contagion, to mention just a few examples.

The term 'microbe' is a broad and somewhat general one, meant to embrace the biological organisms that are characterized principally by their small size. It was first suggested by Maximilien-Paul-Émile Littré (1801–81), the great French lexicographer and linguist who was also trained in medicine, and proposed to the *Académie impériale de Médecine* by the French surgeon Charles Se'dillot (1804–83) and quickly adopted by the French school. 'Microbe' allows an agnostic stance until one is sure of the precise biological nature of the organism under discussion, a particular virtue in the early days of microbiology. Bacteria, molds, viruses, protozoans, and sometimes even small multicellular parasites and mammalian cells in culture are subsumed under this designation. For historic reasons, no doubt, the singlecell algae seem to have remained the province of the botanists and are rarely considered as microbes. Also, although resistance and responses to microbial infections are of great importance in microbiology, many of these phenomena have become the domain of immunology and will not be included here. This article will focus on the history of microbiology since the invention of the microscope for two reasons: first, the new mechanistic philosophy of the seventeenth century provided a context in which to understand microbes, and second, the ability to observe microbes, albeit indirectly with an optical instrument, was essential to the further development of the subject.

Since any brief survey must be selective, this article will emphasize those events and discoveries that are considered common to all microbiological investigations. Some areas have been omitted or treated with less attention that they deserve (e.g., parasitology and mycology), and the history of some newer topics (such as microbial evolution) have been left to the text articles on those subjects. The bibliography includes standard monographs of historical interest, key textbooks that give historical accounts of various topics, and a few references to the literature of the history of biological science and medicine. Articles on the history of microbiology are included in such searchable databases as Medline and History of Science and Technology (Research Libraries Group), both accessible on the Internet.

Microscopy in the Seventeenth Century

The invention of the telescope at the beginning of the seventeenth century quickly led Galileo to his revolutionary astronomical discoveries, and shortly thereafter experimenters in optics produced the first microscope, reportedly demonstrated for the first time in Paris in 1620. These first microscopes were 'simple' in that they had a single lens of high curvature, often a glass bead, and were first exhibited as curiosities. By the mid-seventeenth century, several serious investigations were underway, which employed the microscope to examine the invisible structures, if any, of matter. This interest in the structure of matter was stimulated by the broad seventeenth-century philosophical debates on the mechanistic concept of the universe, which included speculation that matter, animate and inanimate, is made of small particles, some of which function as tiny machines to impart function to the whole. Notable among the seventeenth-century microscopists were Robert Hooke (1635–1703), Nehemiah Grew (1641–1712), Marcello Malpighi (1628–94), Jan Swammerdam (1637–80), and Antony van Leeuwenhoek (1632–1723).

It was Leeuwenhoek who is most remembered today for his voluminous investigations and for the superior quality of his self-made instruments, and who was most concerned with observations on suspensions that contained objects we now consider as the subjects of microbiology. Leeuwenhoek was a local cloth merchant in Delft, Holland, who had little formal education but who developed a passion for lens-making and microscopic observations and descriptions. Through the Delft anatomist Reinier de Graaf, Leeuwenhoek came to the attention of Henry Oldenburg, the secretary of the newly formed Royal Society of London for the Improvement of Natural Knowledge ('The Royal Society'), who began publishing Leeuwenhoek's descriptive studies in 1673. Leeuwenhoek's 'Letters' to the Royal Society span over 50 years of microscopic observations on infusions, body fluids, and a wide range of other materials. His skill as a lens-maker became widely recognized, and his reports were appreciated for his careful descriptions as well as for his technical virtuosity. His studies on human semen and description of spermatozoa (his own) contributed to the seventeenth-century debates on animal generation and the demise of various preformation theories of

reproduction. In his own time, Leeuwenhoek was best known for these contributions, and his observations on microorganisms, now celebrated as the beginning of microbiology, were of relatively little interest and significance in his own time.

Robert Hooke was the other microscopist most credited as a founder of the field of microbiology. Hooke's famous book, *Micrographia*, published in 1665, astounded people with the details of the invisible world revealed by the new microscopes, some of which were devised by Hooke himself. This book contains for the first time illustrations drawn by Hooke of his microscopic observations. The most famous of these, showing the microscopic structure of cork, has been taken as the beginning of the cell theory of life, later developed by Schleiden and Schwann in the nineteenth century. Hooke was able to confirm and extend Leeuwenhoek's results in the presence of members of the Royal Society, thus establishing the credibility of the rather reclusive Dutch cloth merchant.

While Leeuwenhoek's reports on what he called 'animalcules' (little animals) in rainwater and in various infusions indicate that he had indeed seen various common protozoa, yeasts, and some bacteria, he did not extend these observations very much beyond his careful descriptions. Throughout the eighteenth century, dedicated microscopists pursued the study of these objects and refined their descriptions, but all were limited by the optics of the simple microscope: chromatic and spherical aberration, and relatively low magnification. Specimen preparation methods, such as sectioning and staining, were primitive. For example, prior to the introduction of the mechanical microtome in 1770, thin sections had to be cut freehand.

Contemporary ideas about life, matter, and disease did not allow seventeenth- and eighteenth-century microscopic observations to be easily interpreted. Even in the late eighteenth century, Linnaeus was puzzled as to how to treat these little animals in his grand classification schemes. He assigned many of them to the genus and species: *Chaos infusoria*, perhaps indicative of the ambiguous status of microbes at that time.

Spontaneous Generation and Microbes

In parallel with microscopic studies, complementary debates on the origin of living things were intense during the seventeenth and eighteenth centuries. Although these two topics started from quite different points, they would become intimately connected in the nineteenth century, so much that we now think of them as part and parcel of one tradition. Common observations of the apparently spontaneous appearance of insects, worms, and other small creatures (even mice) suggested to many observers that these living beings could arise from nonliving sources such as mud or putrefying vegetable or animal matter. Even the famous chemist and philosopher Jan Baptist van Helmont (1577–1644) believed that mice could arise from grain stored in granaries.

In 1668, Francesco Redi (1626–97) published his investigations to test the belief that maggots and flies arose spontaneously from meat. Redi was a courtier and natural philosopher under the patronage of the Medici Grand Duke in Tuscany and, as such, was expected to present 'observations' and 'demonstrations' for the enlightenment and amusement of the court. At one point, he conducted a series of observations on rotting animal flesh, some portions of which had been protected from the air or from other sources of infection. The interpretation of these 'experiments' was that the maggots, flies, and ova seen in the exposed samples but rarely in the protected samples, did not have their origin from the meat itself, but rather the rotting flesh only served as suitable nest for the growth and nourishment of the eggs of the animals that were deposited there. While Redi is often cited in textbooks as having used or even invented the 'controlled experiment', when his work is viewed in the context of his own time, it is clear that his view of 'experiment' was quite different from the modern interpretation. For Redi, experimentation meant visual demonstration of already 'known' truths.

Despite work such as that of Redi and others, the idea that living beings were continuously being created from more basic material persisted. Georges-Louis Leclerc, Comte de Buffon (1707–88), a famous French naturalist, in his monumental *Histoire naturelle* (1749 et seq.), described his beliefs that all living things contain an indestructible vital principle. Buffon incorporated newer ideas about the chemistry of 'molecules' (small globules or particles) into his theories and regarded spontaneous generation as the result of the intrinsic properties of these organic 'molecules'. The noted British naturalist, John Turberville Needham (1713–81) employed microscopic studies of various infusions, both heated and unheated, both open and closed to the air, and consistently observed the development of many of Leeuwenhoek's little animals. He interpreted such results in terms of Buffon's hypotheses and was a strong supporter of the notion of spontaneous generation. When Needham's work was repeated and extended by the Italian naturalist Lazzaro Spallanzani (1729–99), Spallanzani found that heating was quite effective in preventing the appearance of the little animals, and furthermore, that Buffon's ideas about the vitality of the material present in the infusions, thought to be the precursor of the little animals, were untenable. Spallanzani did many careful experiments with heated sealed and unsealed flasks from which he concluded that exposure to air was the source of the organisms that appeared in the infusions after heating. Neither Needham nor Spallanzani had the microscopical techniques that might have allowed resolution of their disputes. Furthermore, the biological status of the 'little animals' remained unclear, with the result that well into the nineteenth century, the questions of spontaneous generation and 'vital principles' remained unresolved.

As discussed below, motivated by practical concerns with fermentations and disease, Pasteur and others pursued the questions already framed by their eighteenth-century predecessors with newly developed techniques, concepts, and instruments and by the end of the nineteenth century, serious discussion of spontaneous generation waned. The belief in Buffon's vitalism, however, has been more durable, and even the most current textbook writers feel a need to exorcise the ghosts of this eighteenth- and nineteenth-century doctrine by proforma reference to Wohler's famous synthesis of the 'organic' compound urea, from an 'inorganic' cyanate (a reductionistic view that claimed that only living organisms, because of the vital principle, could produce 'organic' compounds). Even in twenty-first century popular culture one can find strains of these eighteenth century ideas.

Classification of Microbes

The biological nature of the animalcules began to attract the attention of naturalists in mid-eighteenth century with the classification of many of these forms by the Danish naturalist Otto Friderich Müller (1730–84), who devised some of the terminology still in use today. He grouped the animalcules into two major groups: those without visible external organs and those with such structures. The first group was divided further into two groups, one of which included five genera, two of which (*Monas* and *Vibrio*) contained bacterial forms. One of Müller's species, *Monas termo*, would become the subject of most nineteenth-century attention, much as the colon bacillus, *Escherichia coli*, has been the paradigmatic species in the late twentieth century.

The science of optics was sufficiently developed by the 1820s to allow construction of compound microscopes with achromatically corrected lenses and some correction for spherical aberrations. Better microscopy resulted in more detailed observations of the microbial world. In some sense, modern classification in microbiology started in 1838 with the work of Carl Gustav Ehrenberg (1795–1876), who published *Die Infusionsthierchen als vollkommene Organismen*, a massive folio of 574 pages with an atlas of 64 hand-colored plates. Many of his drawings reflect his belief that 'Infusoria' (a category that included bacteria, protozoa, rotifers, and diatoms) were small animals and were organized on the same principles as larger animals; thus, he believed all these little organisms had tiny stomachs and were perfect and complete (*vollkommene*) animals. Three of Ehrenberg's 22 families of Infusoria include organisms that are recognizable as bacteria: Monadina, Cryptomonadina, and Vibronia. Vibronia was composed of five genera: *Bacterium*, *Vibrio*, *Spiriochaeta*, *Sprillum*, and *Spirodiscus*. These groups were defined by gross morphology: for example, *Bacterium* included filaments or threads of rod-like forms, which showed transverse divisions. Although Ehrenberg gave detailed descriptions and drawings of many of his observations, it is difficult, if not impossible, to determine with certainty how these organisms would be classified today.

Subsequently, many classifications of microorganisms were proposed, based predominantly on morphologic characteristics with some attempts to incorporate growth characteristics such as growth by transverse division or budding. After Ehrenberg, the next important classification scheme was that of Ferdinand Cohn (1828–98). In 1854, Cohn published an important work in which he suggested that Ehrenberg's Vibronia should be regarded as belonging to the vegetable kingdom rather than to the animal kingdom, and suggested that bacteria were very similar to the well-known microscopic algae. He suggested that bacteria be classified as Mycophyceae or 'Wasserpilze' (water fungus). Cohn's major work in bacteriology, *Untersuchungen über Bakterien* (1872, 1875, 1876), was highly influential and established the outlines of modern bacteriological thought. While Cohn was arguing for the establishment of a taxonomy for bacteria that positioned them within the known biological realm, that is the kingdom of plants, another German biologist, Carl von Naegeli (1817–91), maintained that microscopic fungi may arise spontaneously. Naegeli was an important figure in nineteenth-century biology, and his views gave strong support to an alternative view of bacterial classification, namely the idea that there would be little or no constancy of form in bacteria, which were produced spontaneously from animal or plant precursors. This belief in the multiplicity of forms became known as pleomorphism, and was supported by observations that many fungi seemed to change form depending on conditions and stage in its growth cycle. The late nineteenth century saw intense investigation and debate about these changes or alteration of forms among the fungi and bacteria. In contrast to the pleomorphic hypothesis was the view of Cohn and his followers that each kind of organism had a definite and fixed form. This view became known as 'monomorphism'. Needless to say, the outcome of the monomorphism–pleomorphism controversy was crucial to the future of bacterial classification and taxonomy. An example of this confusion is observed in the work of Wilhelm Zopf (1846–1909), who sided with Naegeli in supporting the pleomorphic doctrine, but implicitly followed the monomorphists in his widely influential classification scheme published in 1885 (*Die Spaltpilze*).

Toward the end of the nineteenth century the classification of microbes was influenced by three major developments: improved morphologic methods (both better instruments and staining methods), pure culture techniques, and better knowledge of the functional activities of bacteria (e.g., pathological actions and fermentations). By the turn of the century, classifications such as that proposed by Migula and Orla-Jensen included properties of bacteria beyond morphology, such as pathogenicity, growth requirements, and staining properties.

The filamentous fungi as well as the protozoa were also included in these early classification schemes, and their distinctive growth patterns, natural histories, and pathologies were recognized. The spore formation by fungi, the colonial growth forms, and the life cycles were characteristics that allowed classification of these organisms to proceed more surely than that of the smaller bacteria. Many of the animalcules of Leeuwenhoek were first called infusoria. The first genus for these infusoria (*Paramecium*) was introduced in 1752 and in 1817 the generic term protozoa was employed by Goldfuss.

While classification methods, stemming from the work of Ehrenberg and culminating in the early work of David H. Bergey (1860–1937) and the Society of American Bacteriologists (*Bergey's Manual of Determinative Bacteriology*), have been of great pragmatic use in categorizing and recognizing bacterial isolates, another goal of classification and taxonomy is to delineate evolutionary relationships. At the light microscopic level, the observable structures of bacteria are relatively uninformative, however, and there has been little confidence that simple size and shape determinations carry much evolutionary weight.

Only with the more detailed investigations and classification of bacteria using biochemical and genetic analyses (genomics) has it been possible to devise classifications that go significantly beyond those of the beginning of the twentieth century. Direct comparisons of the DNA of different organisms became possible with the discovery of nucleic acid 'hybridization' as a method for testing the relatedness of DNA sequences. Prior to the invention of DNA sequencing methods, the extent and rate of DNA helix formation from complementary DNA strands from different microbial species was used, first by Schildkraut, Marmur, and Doty

(1961) to compare the genomes of bacterial isolates. Substantial improvements in gene-based classifications were achieved when Woese (1977) showed that the comparison of the sequences of RNA in the smaller (16S) ribosomal subunit gave meaningful classificatory information. Since the aim of most systems of classification is to reflect evolutionary relationships, such gene-based schemes were highly satisfying. The comparisons of 16S RNA sequences (RNA sequencing was technically more advanced than DNA sequencing methodologies in the 1970s) allowed Woese to propose a novel group of evolutionarily ancient microbes, which he termed Archaea. He proposed that all life be classified into six kingdoms (Eubacteria, Archaeobacteria, Protista, Fungi, Plantae, and Animalia). With the development of rapid methods for the determination of entire genomic DNA sequences since the late 1980s, the comparison and classification of microorganisms has become an industry, based almost entirely on gene relatedness. By 1990, Woese had revised his classification to three 'Domains' rather than 'Kingdoms' (Bacteria, Archaea, and Eukarya). Viruses, however, still resist attempts at rational classification into a single, consistent system.

Contagion

The periodic and widespread occurrence of disease in populations has been noted by historians for several millennia. Both popular and medical accounts abound with descriptions, explanations, and prophylactic advice about epidemic diseases. Many of these accounts suggest that disease is transmissible from an afflicted person to a healthy person, that is, the disease is contagious. Although 'contagious', in modern thinking, almost always implies 'infectious', this is not at all the way the notion of contagion should be read in these older accounts. Without the knowledge of microbes and their relation to disease, the concept of 'infection' is especially problematic. Instead, contagion sometimes implied active maliciousness such as the 'evil-eye', hex-casting, or other such magical practice. Alternatively, the contagion could reside in local conditions such as 'foul' air, or on the clothing or other belongings of the afflicted person, or emanate from decaying material or earth. Thus, the notion of contagion was broad and flexible.

While much has been written on the history of epidemics from the Plague of Athens in 430–425 BCE (Thucydides) to AIDS and SARS, and many writers have tried their hands at retrospective diagnosis and search for precursors to modern ideas of infectious disease, the small book usually called *De Contagione* by Girolamo Fracastoro (1478–1553) is usually taken as the first, more or less clear, recognition that a contagious disease might be transmissible by some sort of 'infectious' agent. Fracastoro treats three types of contagion: by contact alone, by fomites (things 'which are not corrupted themselves, but are able to preserve the original germs and give rise to their transference to others'), and by contagion at a distance. In spite of Fracastoro's rather clear exposition, however, his ideas seem to have lain fallow for several centuries. Contagionist doctrines, while held by many scientists, did not develop in the direction of infectionist beliefs until a plausible mechanism, that is microbes, was known.

Germ Theories

While many of the early microscopists speculated that their little animals might be related to disease, fermentations, and putrefaction, such ideas did not take hold partly because the existing concepts of these phenomena had no way to incorporate microbes into their explanatory schemes. While the diligent historian can find many examples of writings that appear to be precursors to modern germ theories, it is quite clear that they represent a rather silent or ignored tradition in medicine and biology in the seventeenth and eighteenth century.

As the biological understanding of bacteria developed in the nineteenth century, and as scientists turned more and more to physiology and 'animal chemistry' for understanding of biology and medicine, the newer findings about bacteria found their applications. No longer content with explanations of diseases based on miasmas, supernatural retribution for sinful behaviors, and simple environmental conditions, late eighteenth- and early nineteenth-century thinkers looked for causes of disease based within the body itself, in its function, normal, and deranged. These explanations often incorporated specific aspects to account for the contagiousness of certain diseases. The process of fermentation was so important and widely studied that it formed the model by which other biological processes were conceived. Thus, digestion was seen as analogous to fermentation. Likewise, the processes of putrefaction, and by extension, tissue degradations in abscesses, for example, were thought to be related to fermentation. The great German chemist, Justus von Liebig (1803–73), conceived of disease as a putrefaction of tissue produced by nonliving (yet 'vital') substances (which we now recognize as enzymes, *ferments* in French) with the production of toxins. These toxins, when transferred to another individual, could induce further putrefaction 'by contact'. Such a mechanism could explain both contagion and physiological effects without the need for living, infectious agents. In Liebig's theory, fermentations, too, could be brought about by introduction of the nonliving *ferments* to suitable circumstances, for example, in wine-making.

Debate on the theories of contagion thus evolved into investigation of the biological processes of both fermentation and digestion in the mid-nineteenth century. As might be inferred, too, these debates were intimately related to the controversies over spontaneous generation and vitalism mentioned above. Did fermentation (and by extension, disease) require the presence of living organisms? Was fermentation a strictly chemical process, or did it require some essentially 'vital' component? If fermentations always required living organisms (yeast), where did the yeast come from in the apparently spontaneous fermentations seen in wine- and beer-making?

From his studies on the fermentation of beer and wine, Louis Pasteur (1822–95) concluded that the agent that is responsible for alcoholic fermentation is a living organism, yeast, which must be introduced either accidentally or intentionally. Occasional accidents of fermentation ('diseases' of wine and beer) occur when the wrong organism is present. This pathway of experimentation led Pasteur to strongly attack the belief in spontaneous generation. His vigorous experimentation and even more vigorous rhetorical activities led to his fame as the slayer of the doctrine of spontaneous generation. The English physicist, John Tyndall (1820–93), provided strong support for Pasteur's ideas by his investigation of dust and small particles in the air as a source of the contaminations in experiments, which claimed to show the existence of spontaneous generation.

Along with studies of 'diseases' of fermentations, Pasteur undertook the study of a disease of silkworms that was causing severe economic difficulties for French silk producers, and in 1866 found the 'cause' of this disease to be a specific microbe. By the mid-1870s, Pasteur had come to believe that all contagious diseases were caused by specific microbes, a grand generalization that had many versions, which now go under the rubric of 'germ theories of disease'.

Pasteur devised methods for preparation of pure liquid cultures of bacteria by serial transfers at high dilution, and exploited such pure culture techniques to investigate the role of bacteria in disease and later to devise protective vaccines.

A related problem also engaged the attention of nineteenth-century physicians: the nature and cause of diseases variously called putrid intoxication, septicemia, surgical fever, and pyemia. Experiments based on early belief in toxins showed that these diseases were often transmissible by inoculation of blood from one animal to another. Pus from a human wound could induce disease in animals, for example. The precise relationships between pus globules, white blood cells, and other components of blood were unclear. Casimir-Joseph Davaine (1812–82) examined the blood of animals with anthrax and septicemia and reported that bacteria were only present in the blood of diseased animals. Much work of this sort from 1850 onward supported the association between the presence of bacteria and the occurrence of disease. Davaine extended this work to deliberate inoculation experiments with graded injections of material from sick animals and showed that the transmissible agent (called the 'virus' in nineteenth-century terminology) could be titrated and that different animal species varied in their susceptibility to the virulent agent. Davaine's work attracted great interest in France and elsewhere, yet some investigators interpreted this work to show that the bacteria were considered a consequence of the disease rather than a cause.

Theodor Albrecht Klebs (1834–1913), working in military hospitals in Karlsruhe, studied septic deaths from gunshot wounds and found bacteria of different forms present in almost every case he examined. He added much to the knowledge of wound infections and devised several approaches to the study of wound infection, which were soon adopted by Koch.

Robert Koch (1843–1910) was a medical practitioner in the small town of Wollstein in Posen, where he undertook the study of wound infections to determine if they were of parasitic (bacterial) origin. He conducted animal experiments and self-consciously considered just what kind of experiments he must do to prove, as conclusively as possible, that the wound infections that he produced in animals by injection of pus were, indeed, caused by the bacteria found in the pus. Koch was aided in his work by newly available aniline dyes for staining samples, by the newly available Abbe' microscope illuminator, and by the fine oil-immersion lenses made in Jena by Carl Zeiss. In his publication, *Untersuchungen über die Aetiologie der Wundinfektionskrankheiten*, he clearly raised the standards for the study and description of the relationship between bacteria and disease. In spite of the minor stir that this publication caused, many physicians remained unconvinced. Similar investigations were carried out by many other workers, including Alexander Ogston (1844–1929) in Scotland and Daniel E. Salmon (1850–1914) in America.

Koch undertook the study of the life history of the anthrax bacillus in which he noted the formation of spores, which were especially heat-resistant. He immediately realized the relevance of the spore form both from an experimental point of view as well as from the epidemiological standpoint. Koch communicated this work to Ferdinand Cohn, a leader in the German academic world, who recognized its importance and arranged for its publication. From this work on anthrax, Koch became widely recognized as a masterful experimentalist and creative thinker.

Early in his research, Koch recognized the need for better cultivation and identification methods in bacteriology and he worked hard to develop the tools he saw as essential. Both his new staining methods and his improvements of the methods of solid surface cultures led to major new advances in his research work. He devised fixation methods, which preserved the morphology of the bacteria and thus was able to study the organisms in a nonmotile form. He tested a wide variety of fixatives and stains (much of this work based on the early studies of Paul Ehrlich) and was able to obtain preparations far superior to any previously available. Koch also pioneered the use of photomicrography, which had an important role in helping spread his theories as well as convince his critics.

As early as 1865, there had been prior attempts to obtain pure cultures of bacteria by growth of individual 'colonies' on solid medium but these were generally unsatisfactory. In 1881, Koch reported that he could grow individual colonies of bacteria on the sterilized cut surface of a potato slice and soon he followed up on prior work by Oscar Brefeld, who laid the theoretical and practical foundation for work with pure cultures. Koch realized that what was needed was a medium that was sterile, transparent, and solid. Initially, he found gelatin to be very useful and later employed the more stable carbohydrate, agar-agar, as the gelling agent in the medium. At first the medium was simply poured on a glass plate and allowed to gel, but soon Koch's assistant Richard Julius Petri (1852–1921) made slight modifications and introduced the flat dish with an overhanging lid (Petri dish), still in use today.

The solid surface culture of bacteria was a revolutionary advance in technique that had major consequences. With this method for pure culture isolation, many of the ambiguities in the monomorphism–pleomorphism debate were resolved. Bacterial identification and classification became easier and more certain. Most importantly, Koch was finally able to affirm the identity of a specific bacterial type with the virulent agent in the blood, pus, or tissue extracts in his animal inoculation experiments.

Koch and several other thoughtful advocates of germ theory doctrines of disease were concerned about the knowledge claims they were making: what experimental evidence was needed to prove that a specific bacterium was the cause of a specific disease? Over a period of several years (1876–82), Koch evolved a set of criteria for such evidence. In his 1878 paper on wound infections, he gave a set of three rather weak criteria, but in 1882 in his landmark paper on the etiology of tuberculosis, he stated: “To prove that tuberculosis is a parasitic disease, that it is caused by the invasion of bacilli and that it is conditioned primarily by the growth and multiplication of the bacilli, it was necessary to isolate them [free] from any disease-product of the animal organism which might adhere to them; and, by administering the isolated bacilli to animals, to reproduce the same morbid condition which, as known, is obtained by inoculation with spontaneously developed tuberculous material.” Later versions by Koch and textbook authors have combined this statement with some of Koch’s other writing to synthesize three criteria which have come to be known as ‘Koch’s postulates’. (Apparently, however, he never referred to these criteria as ‘postulates’.)

In America, Daniel Salmon was investigating the cause of hog cholera and had developed his own set of criteria for disease causation by bacteria. In addition to the criteria that Koch proposed, Salmon believed that the causal connection required the added demonstration that the killing of the bacteria was curative of the disease.

In the final decades of the nineteenth century, with the new methods available and the conceptual framework of Koch, Pasteur, Davaine and others, advocates of germ theories of disease were hard at work ‘hunting microbes’. With each success of associating another disease with a specific pathogenic organism, the rush to find bacterial causes for all disease increased. In addition to bacterial causes of cancer, there even were reports of bacterial causes for mental disorders.

Applications of the Germ Theories

With a clearer understanding of the causes of contagious diseases, there was a strong impetus to use this knowledge in ways to treat or prevent the disease. These efforts took several forms: sanitation and public health, asepsis and antisepsis, and preventive vaccinations. Specific chemotherapy came later.

Germ theories of disease fit well with the program of the nineteenth-century public health movement with its emphasis on ‘filth’ as the cause of disease. From the mid-century work of the lawyer-sanitarian Edwin Chadwick (1800–90) in England, it was believed that mortality rates, and perhaps health in general, could be affected by sanitary reform. Bacteriologists noted that the very places and conditions considered ‘filthy’ were generally the places and conditions where bacteria were likely to flourish. It is no surprise, then, that many of the leading nineteenth-century bacteriologists were interested in water supply sanitation, food quality control, and sewage and waste treatment and disposal. In America, William T. Sedgwick (1855–1921) was the most accomplished sanitary scientist and water bacteriologist of his day, and as chair of the Harvard – MIT School for Public Health Officers, he educated a generation of public health-oriented bacteriologists.

In England, Joseph Lister (1827–1912) was the most active advocate for the application of Pasteur’s germ theories to the practice of surgery. In 1868, he reported on his use of antisepsis (not asepsis) during surgery to prevent the occurrence of surgical wound infections. He employed phenol (carbolic acid) in an oil suspension. His results and his approaches to surgical cleanliness initiated a new era in surgical practice and led to a dramatic decline in postsurgical septic mortality. Lister’s work led others to study antiseptics in detail, and Koch soon was able to make the important distinction between agents that simply arrest bacterial growth without killing (bacteriostatic agents) and those that are able to kill bacteria (bacteriocidal agents).

Germ theories did not find application only in medicine. Crop diseases, especially those involving fungi, were recognized as infectious in origin. As early as 1767, Giovanni Targioni-Tozzetti (1712–83) proposed that rusts of cereals might be caused by infection with microscopic fungi and by 1807, Isaac Be’ne’dic Pre’vost (1755–1819) had demonstrated experimental smut infections and showed that copper sulfate solutions could be used to disinfect plant seeds. The biological study of fungi led to better understanding of their life cycles and of the alternation of hosts required by some organisms. For example, by 1865 Anton de Bary (1831–88) explained the role of barberry plants as an intermediate host in wheat rust, and recommended that rust epidemics could be controlled by elimination of the practice of using barberry hedges near wheat fields. Ergot of rye was another important pathogen, which led to widespread human illness in certain years when the infection was prevalent.

Several fungi (mildews) were recognized as pathogenic to grape vines by the mid-nineteenth century and direct treatment of vineyards with agents known to kill the organisms were developed. Copper sulfate and lime suspended in water were widely employed and became known as Bordeaux mixture.

Human diseases caused by fungi and protozoa were also recognized in the nineteenth century. Skin diseases (dermatomycoses) such as favus (Scho’nlein, 1839) and thrush (Langenback, 1839) were shown to be related to specific fungi (*Achorion schonleinii* and *Candida albicans*, respectively), and the monograph *Histoire Naturelle de Ve’ge’taux Parasites* (1853) by Charles-Phillippe Robin (1821–85) was a landmark summary of early medical mycology. In 1910 when Sabouraud devised a medium on which pathogenic fungi could be easily cultivated, the development of medical mycology greatly accelerated.

The role of protozoa in disease was suggested early by observations such as Alphonse Laveran’s (1845–1922) discovery of a specific organism in the blood of malaria patients in 1880. Later Giovanni Battista Grassi (1854–1925) and Ronald Ross (1857–1932) were able to discover the role of the mosquito in the transmission of malaria (1890s). Ross and his collaboration with Patrick Manson (1844–1922) exemplify the way the field of tropical medicine developed from the need to better understand newly encountered diseases during nineteenth-century European colonial expansion.

Other forms of microorganisms were found to be the cause of disease as well. For example, in the early twentieth century, small, bacteria-like, obligate intracellular forms now known as *Rickettsia* were found to be the infectious agent in diseases such as louse-born epidemic typhus (Charles Nicolle, Howard Ricketts, and Stanislaus Prowazek) and Rocky Mountain spotted fever (Ricketts). Chlamydiae, another group of obligate intracellular pathogenic forms, thought to be distantly related to Gram-negative bacteria, were recognized in 1952 as distinct from large viruses.

Mycoplasmas, the smallest known free-living microbes, are a pleomorphic and widespread group of organisms. Since they often pass through conventional filters, they were originally classified as filterable viruses. The first known mycoplasma disease was pleuropneumonia of cattle, which was studied by such luminaries as Pasteur (1883), Nocard (1898), and Bordet (1910). From this example, mycoplasmas came to be called 'pleuropneumonia-like organisms' or PPLo until recently. One isolate from primary atypical pneumonia in humans was propagated in chicken embryo tissue and was known eponymously as the Eaton agent (1944).

Perhaps the most dramatic advances that followed the new understanding of germ theories of disease were those involving preventive vaccination. The general phenomenon of resistance and immunity had been recognized for a long time, but beyond general knowledge that a prior smallpox attack protected the individual in a subsequent epidemic, and that some diseases seemed to be species-specific, there seemed to be no way to understand or manipulate these phenomena except in the unusual case of smallpox.

Smallpox had long been deliberately transmitted by contact from a sick person to a healthy person with the intent of inducing a (hoped for) mild case of the disease, which would then result in lifelong immunity. This practice was called 'variolation', and was introduced to England and America in the early eighteenth century apparently from the Middle East, although this practice was widespread in India and East Asia before that. In 1778, Edward Jenner (1749–1823) started his studies on the role of cowpox infection in humans as a protective experience against smallpox. He was following an apparently well-known local folk belief, but through his careful work and clear exposition in his report of 1798 he gave wide attention to the effectiveness of this procedure, called 'vaccination' (Latin: vacca, cow), in protection against smallpox.

Pasteur seemed to have been influenced by notions of such cross-immunity resulting from similar but slightly different diseases, and when he was called upon to study chicken cholera in France, he saw an opportunity to apply this notion to another disease. While studying the bacteria associated with chicken cholera, Pasteur transferred the cultures serially and noted that the virulence of the cultures for killing inoculated chickens decreased with the number of laboratory culture transfers. He termed this decrease 'attenuation'. Apparently, he sought to 'challenge' some birds that had recovered from an inoculation of an attenuated culture with a highly virulent form of the bacterium and discovered that the attenuated inoculum had produced strong immunity to the lethal form of the disease. From these observations, Pasteur went on to formulate rather elaborate and complex theories of immunity and attenuation. These theories are no longer accepted, but they stimulated much important research on vaccines, immunity, and the nature of bacterial virulence. Out of this work came Pasteur's famous rabies vaccine as well as his famous work on anthrax vaccine, which resulted in highly publicized trials of his vaccine on a herd of sheep, some cows, and a goat at Pouilly-le-Fort in 1881.

Vaccine development has proceeded from this time partly along the empirical approach used by Pasteur and his colleagues, and partly along the more theory-based approaches developed by Paul Ehrlich (1854–1915), Emil von Behring (1854–1917), and later immunologists. In trying to explain the mechanisms by which vaccines induce immunity, early research focused on the interaction of the bacterium and the blood. Richard Pfeiffer (1858–1945) noted that the serum of immune animals was able to cause lysis of the specific bacterium against which the immunity was directed, and later Jules Bordet (1870–1961) discovered that multiple serum components (complement) are involved in the immune cytolysis (cell lysis) phenomenon. The antibody molecules induced in response to vaccine treatment were studied intensely, and Ehrlich explained the specificity of the antibody-antigen interaction in terms of the structural features of each of these components. The science of immunology took new directions with the landmark studies of Karl Landsteiner (1868–1943) on the specificity of serological reactions.

While germ theories of disease gradually gained adherents in the last two decades of the nineteenth century, and hunts were underway for microbes in every conceivable situation, doubts remained. For example, the discovery of the healthy carrier state in cholera by Koch and his colleagues provided a serious challenge to germ theories. When Max Von Pettenkofer (1818–1901), a major critic of the germ theories, drank a pure culture of cholera vibrios and remained healthy, Koch registered his worry that the germ theory had suffered a serious setback. Vaccination campaigns were not always readily accepted by the public and the validity of vaccination for a variety of diseases was doubted not only by many layperson, but also by many physicians as well. The new science of microbiology did not simply march triumphantly into the clinics and up to the bedsides to take over medicine by force of reason, superior science, and undeniable successes.

Antimicrobial Therapies

Following on the work of Lister on antiseptics, many microbiologists undertook searches for agents, which could be used to kill bacteria *in vivo*. Various attempts to use chloroform, iodine, thymol, and many other disinfectants were reported. Paul Ehrlich reasoned that just as there were dyes as well as antibodies that are specific for certain bacteria, there must be other kinds of chemicals that can bind to, and inactivate, specific microbes. His search for such compounds led to the discovery of several drugs useful in the treatment of protozoal and spirochetal diseases between 1905 and 1915. The arsenical compound, arsphenamine (salvarsan, compound 606), was used to treat syphilis until the advent of penicillin. In a continuation of Ehrlich's approach, another product of

the dye industry, prontosil, was introduced as an antibacterial agent by Gerhard Domagk (1895–1964) in 1935. This compound was metabolized to sulfanilamide, a fact which when recognized, led to the development of many new sulfa drugs.

While investigating lysozyme, a bacteriolytic enzyme present in some body fluids and abundant in egg white, in 1929 Alexander Fleming (1881–1955) noted that cultures of the mold *Penicillium* produced a substance (penicillin) that inhibited the growth of *Staphylococcus* on culture plates. Although Fleming was unable to purify and more fully characterize penicillin, an accomplishment of Howard Flory and Ernst Chain in 1940, his finding suggested to others that saprophytic fungi might be a useful source of antimicrobial agents. René J. Dubos (1901–82) discovered one such product, tyrothricin, which has the peptide gramicidin as its active component. This success marked the beginning of a search for microbial products that can be used as antimicrobials. The discovery of streptomycin by Selman A. Waksman (1888–1973) and Albert I. Schatz (1920–2005) in 1944 was the beginning of a cornucopia of useful antibiotics. Potent microbial toxins, such as the highly carcinogenic aflatoxin from *Aspergillus flavus*, cholera toxin and botulinus toxin, among many others, have been discovered.

Public Health

The origins of public health microbiology are rooted in the earlier concerns of public health with sanitation and with control of epidemic diseases. The linkage of epidemiology and microbiology was a natural outgrowth of germ theories of disease and the general understanding of the distribution of microbes in the environment. W. T. Sedgewick wrote a key text in 1902, *Principles of Sanitary Science and Public Health*, which described the examination of drinking water for microscopic forms (bacteria, diatoms, algae, and infusoria), the use of coliform counts to assess the effectiveness of water filtration and the processing of sewage involving microbial actions.

Major problems in public health included food microbiology, such as testing milk cows for tuberculosis (1889), epidemics, exemplified in *Sources and Modes of Infection* published in 1910 by Charles V. Chapin (1856–1941), and sanitation testing through the establishment of government microbiological laboratories.

Partly in response to the cholera epidemics in the United States in the nineteenth century, several major cities established permanent, active boards of health by the end of the century. The US Public Health Service established the Laboratory of Hygiene in a Marine Hospital on Staten Island in 1887, to serve as a cholera study unit. This laboratory evolved into the National Institute of Health in 1930. Governmental laboratories, both municipal and state, served as diagnostic centers for physicians and public health officers to carry out microbiological isolations, diagnostic identification, and community surveillance. In New York, for example, the Public Health Laboratory under Herman Biggs, Haven Emerson, and William H. Park provided diagnostic services, bacteriological screening of food handlers and of school children, and later supervised immunization programs. These public health laboratories combined diagnostic microbiology, epidemiology, field work, quarantine, and research to define the current scope of public health microbiology.

Clinical Microbiology

Microbiology in medicine often was in the professional domain of pathologists, because in the period before effective antimicrobial therapies, many infections were studied in the autopsy room after the demise of the patient. Within the hospital, then, microbiology grew up along with pathology, and until the middle of the twentieth century these two disciplines were frequently practiced in the same department, usually called 'pathology and bacteriology' recognizing the seniority and dominance of pathology. Starting in the early twentieth century, however, bacteriology began to claim its independence from pathology. Educational programs in bacteriology were separated from pathology, laboratory practices differentiated bacteriology from anatomic pathology, and professional boundaries began to develop.

The birth of medical microbiology in association with pathology probably made it relatively easy for microbiology to take on service roles in examination of clinical specimens as had pathology. Many of the early microbiologists had been trained as physicians and they could relate well to their clinical colleagues and argue for the importance of increased bacteriological study of patients prior to death. Especially with the discovery of antimicrobial therapies, starting with serums and vaccines, and later with bacteriophage and then sulfas and antibiotics, the role of the bacteriological laboratory in clinical medicine became central to the practice of medicine. With the advent of specific antimicrobial therapy, it became crucial to know the identity and antibiotic sensitivities of the infectious agent isolated from the patient. This demand for accurate and rapid microbiological analysis of clinical samples continues to the present, with great emphasis put on technological innovation and the rapid processing of massive numbers of samples.

Agricultural Microbiology

Microbiology developed from an early stage around both the practices and the products of agriculture. The study of the microbes in the soil, the microbiology of animal health, and the processes of food production all were important from the very beginning of the field.

While soil microbiology has developed into its own discipline, it originated in questions relating to the chemistry and fertility of soil and broad questions about the role of soils in chemical processes involving nitrogen. The sources of ammonia and nitrates in the soil puzzled chemists such as Pierre-Eugène-Marcelin Berthelot (1827–1907) who soon surmised that it was the microbes in the soil which were responsible for the ‘fixation’ of nitrogen into ammonia and nitrates. Other nineteenth century microbiologists found that the root nodules in legumes were symbiotic colonies of bacteria with the special capacity to reduce atmospheric nitrogen to ammonia and other forms that were then available to the plants for assimilation. Sergei Winogradsky (1856–1953), the Great Russian microbiologist, focused on soil microbiology and through his work and that of his research school, developed our current understanding of microbial nitrogen fixation, a process essential for life on earth. The Dutch school of general and comparative microbiology, founded by Martinus W. Beijerinck (1851–1931) and his protégé, Albert Jan Kluyver (1888–1956), grew from this same interest in soil and environmental microbiology.

Both the diseases and special biology of animals and plants provided important opportunities for crucial advances in microbiology. Pasteur refined his concepts of the role of microbes both in fermentation and in disease by his studies on the ‘diseases’ of beer and wine, and in his study of diseases of silkworms, beehives, and chicken flocks, not to mention the famous case of anthrax. Such diseases afforded chances to carry out investigations on animals that would not have been possible in analogous human diseases.

Animals also provided novel biological opportunities because of their specialized physiology.

The symbiotic relationship between bacteria and digestion in ruminants was an important advance in the understanding of animal husbandry. The production of silage by microbial action furthered the knowledge of both animal nutrition as well as the science of fermentation.

The role of microbes in the processing and preservation of foods provided another path of investigation in microbiology. Both the use and the avoidance of microbes in food technology has been crucial to improving food yields, reducing spoilage, and avoiding illnesses associated with food contamination. Food preservation by microbial action is ancient, familiar examples being wine, beer, and cheese making. The use of vinegar, a product of bacterial action, and salt to inhibit contamination in pickling is also an ancient practice. Smoking and drying fish and meat are traditional practices to limit bacterial growth.

Virology

One of the basic methods for ‘microbe hunting’ from the very early period of microbiology was filtration. Very fine filters were designed to remove small particles such as microbes to sterilize fluids and to characterize the particulate nature of infectious materials. Two widely used filters were the Chamberland filter and the Berkefeld filter. The former, named for Charles Chamberland (1851–1908) of the Pasteur Institute, is a tube of unglazed porcelain (a ‘candle’ filter) through which liquids can be passed under pressure. The latter is a column of diatomaceous earth (Kieselguhr), named for the owner of the mine near Hannover, which produced the material. If an infectious agent was not retained by such a filter, it was termed ‘filterable’ (sometimes spelled filtrable) or ‘filter-passing’. Of course, both particulate and soluble substances could be ‘filterable’.

The term ‘virus’ was initially used to designate the component of an inoculum, which was the causative agent of the disease (Latin: *virus*: poison, venom). The term was generically applied to bacterial agents as well as other organisms. One of the main goals of the early germ theorists was to isolate and identify the virus that was present in blood, tissue extract, sputum, or stool sample, which could transmit disease when inoculated into susceptible hosts. Soon it was found that some of these viruses of disease could pass through the filters, which were known to retain bacteria. These agents of disease came to be known as ‘filterable viruses’ to distinguish them from all the other viruses. Since the nature of the filterable viruses was obscure in the early part of the twentieth century, the term ‘filterable virus’ persisted in the literature until the 1930s; for example, the classic 1928 text, edited by Thomas M. Rivers (1888–1962), was entitled *Filterable Viruses*. Shortly thereafter, common usage came to drop the qualifier ‘filterable’ in favor of simply ‘virus’ to designate the filter-passing forms of infectious agents.

The first disease that was recognized as being caused by a filter-passing agent was tobacco mosaic disease. This disease was economically devastating to Dutch tobacco growers and its cause was actively studied in Holland starting with the work of Adolf Mayer (1843–1942) in 1879 who was able to transmit the infection but failed to find the causative virus, believed to be a bacterium. Martinus W. Beijerinck worked on tobacco mosaic disease off and on for over a decade and by 1898 he found that the virus was ‘filterable’, that it would diffuse through agar, and that it was serially transmissible. For the virus of tobacco mosaic disease, Beijerinck proposed a new category of agent, living and nonparticulate, a *contagium vivum fluidum*. A few years earlier, Dimitri Ivanovski (1864–1920) had shown the filterability of the agent of tobacco mosaic, but because he was able to transfer the disease via bacterial colonies (probably contaminated with residual filterable virus), Ivanovski believed that tobacco mosaic was a bacterial disease.

The nature of filterable viruses as represented by the tobacco mosaic virus (TMV) was controversial. Some thought of the agent as chemical, perhaps a cellular component, while others thought of it as an ‘ultramicrobe’, an organized living being, too small to be seen in the microscope.

Subsequent attempts to study TMV were hampered by the inability to grow the agent outside of the infected plant, and by difficulties in its detection and quantification. Some of these difficulties were overcome by the preparation of large amounts of infected plant material by Carl G. Vinson (1927) and an improved quantitative assay by Francis O. Holmes (1928). In 1935 Wendell Stanley (1904–71) reported that he had crystallized TMV, a startling observation that forced reconsideration of the concept

of 'living', 'infectious', and 'microbe'. Stanley and his coworkers, based on their chemical analyses at the time, believed that TMV was composed only of protein. Since crystallization was the standard criterion for purity of organic compounds and by extension, of proteins, this work was interpreted to show that filterable viruses such as TMV were self-replicating, infectious proteins. Indirectly, of course, this conclusion strengthened the belief that genes, too, were protein molecules. The RNA component of TMV (about 7%, by weight) was soon found by Frederick Bawden (1908–72) and N. W. Pirie (1907–97) in England. Still, the controversy over viruses remained. How did they replicate? Where did they originate? Were they autonomous or part of the cell? Should they be conceived as macromolecules or as microbes?

From the beginning of the twentieth century, filterable viruses were found as the causes of many contagious diseases that had resisted bacteriological etiologies: Herpes labialis (fever blisters), influenza, and poliomyelitis, to name a few human diseases; hog cholera, rabies, and cowpox among the mammalian diseases; and leukemia and sarcomas in birds. It was eventually realized that one of the defining, although 'negative', characteristics of all these viruses is that they are obligate intracellular agents, and they cannot be grown independently of their host or at least host cells. This realization finally led to searches for better ways to grow and assay viruses apart from animal or plant inoculations. The tissues of the embryo in the chicken egg became a convenient and standardized growth and assay medium for many viruses and are still in use today for some purposes. Egg cultures of many viruses were studied by Ernest Goodpasture (1886–1960), who perfected this method in the 1930s. By the 1950s the ability to grow explanted mammalian cells in various culture media ('tissue culture' or 'cell culture') provided a new and improved way to grow, assay and study many viruses. In particular, the growth of poliovirus in monkey kidney cells in culture in 1949 by John Enders and colleagues led to better understanding of this virus and its ultimate control through preventative immunizations first with a killed preparation of poliovirus (the Salk vaccine) and later a live, attenuated orally effective vaccine (Sabin).

A special class of filterable agents was discovered in the first decade of the twentieth century, which deserve special mention: the cancer-causing viruses. This group of viruses, not related by structure, pathogenesis, or genealogy, has provided important insights into the interplay between genes, viruses, and cells. In 1911, Peyton Rous (1879–1970) observed that a cell-free filtrate prepared from a chicken sarcoma could induce similar sarcomas when inoculated into other chickens. Likewise, in 1908 Ellerman and Bang suggested that leukemia in fowl could be caused by inoculation with a filterable agent. The notion that cancer might be an infectious disease was so potentially frightening to the public that Rous tried to avoid any unnecessary publicity of his work, and eventually abandoned it. In searches for the causes of cancer, there were many reports of bacteria associated with various malignancies, but only the filterable viruses seemed to emerge as possible causal agents for animal cancers. (One possible exception is the mucosa-associated lymphoid tissue (MALT) lymphoma, associated with *Helicobacter pylori* infection of the stomach. In plants, the causative role of *Agrobacterium tumefaciens* is causing tumor-like proliferation in well established.) By the mid-1950s several classes of viruses had been identified, which could induce cancers in experimental animals. However, it was not until much later that candidate human tumor viruses were isolated. Most of these tumor viruses have RNA genomes, which can be copied into DNA and integrated into the cell genome to reside there in symbiosis while causing a neoplastic transformation in many cases. Interestingly, the organism associated with AIDS, human immunodeficiency virus (HIV), first identified in the 1980s, turned out to be in this same retrovirus group of viruses, although HIV does not cause tumors.

Bacteriophage are now recognized as viruses that infect bacteria; however, originally they were not believed to be similar to the filterable viruses. In 1915 F. W. Twort (1877–1950) in England reported 'glassy transformation' of micrococci, which contaminated his attempts to grow vaccinia virus on cell-free culture media. This phenomenon of glassy transformation was serially transmissible and killed the bacteria. Twort's interpretation of this phenomenon was unclear and ambiguous. In 1917, Félix d'Herelle (1873–1949), a French Canadian working in Paris, independently observed lysis of dysentery cultures, and noted that the lytic principle was filterable, and that something in the lysed culture could produce clear spots (plaques) on confluent bacterial cultures. This lytic principle was serially transmissible and by d'Herelle's interpretation, particulate. He conceived of this agent as a microbe, which parasitizes the bacteria, that is a virus of bacteria. Not only did he devise the quantitative plaque counting method, but he also worked out the basic life cycle of this agent, which d'Herelle termed bacteriophage (although long known by the noncommittal term 'Twort-d'Herelle Phenomenon'). The biological nature of bacteriophage was hotly debated for about 20 years, with the majority view in opposition to d'Herelle's ultravirus hypothesis and in favor of some sort of endogenous autocatalytic process. Only when uniform virus particles were observed by electron microscopy in 1940 did the particulate view of bacteriophage become widely accepted.

D'Herelle and Twort engaged in a 10-year polemic over the issue of priority of discovery of bacteriophage which tarnished the reputation of both scientists. Twort did not pursue phage research, and d'Herelle focused mostly on the application of phage as therapy and prophylaxis for infectious diseases in the era before antibiotics. While this application seemed to offer promise and is now being reexamined, it was eclipsed by the marvels of the new antibiotics in the early 1940s.

The study of phage from the biological point of view has been central to the development of molecular biology. Viruses in general, and phage in particular, were recognized as very useful 'probes' for cellular processes which they exploit during their life cycles. The problem of gene duplication, especially, seemed amenable to study with phage. Both in the United States and in France, phage research since the 1940s was directed at understanding what happens during the half hour or so that it takes for one infecting phage to produce a hundred progeny in an infected bacterium. This was the basic research program that Max Delbrück (1906–81) set for the American Phage Group. The work of this loosely defined school of research has been instrumental in deciphering much about the nature of the gene, mutagenesis, recombination, and gene expression and regulation.

In virology the electron microscope has had a major impact. Prior to about 1940, viruses were defined by their small size, by filtration and diffusion properties, and their invisibility in the light microscope. The electron microscope was invented in Germany

in 1931 by Max Knoll and Ernst Ruska, and by the late 1930s had sufficient resolving power to demonstrate the particulate nature of several viruses, including bacteriophage. The RCA company designed and constructed the first electron microscopes in the United States, and in 1942 Thomas Anderson (1911–91) and Salvador Luria (1912–91) used such an instrument to examine phage in detail. The ability to visualize viruses at last (albeit indirectly) brought some long-awaited unity to virology, and bacteriophage were finally accepted as viruses of bacteria.

Microbial Physiology

With the recognition of the role of microbes in ancient processes such as fermentations and other types of food processing (cheese, bread, soy sauce, and silage), a better understanding of these uses of microbes and their by-products was possible. Antibiotics represent just one aspect of this exploitation of microbial metabolism. Several groups of researchers, including Sergei Winogradsky and Martinus Beijerinck, emphasized the diversity of microbial forms and metabolism and pioneered the fundamental study of the physiology of bacteria. These studies led directly to the use of microbes to produce useful 'secondary metabolites', compounds such as glycerol, lactic acid, pigments, and other intermediates that are products of the metabolism in specific organisms. Soil and dairy microbiology developed in colleges of agriculture and in the agriculture experiment stations established in the United States, in the late nineteenth century. This work promoted the understanding of microbial processes used in cheesemaking, such as the use of specific molds to achieve the best products, in spoilage of foods, and in the use of manure, legumes, and composts to fertilize the soil. By the 1930s this work on bacterial metabolism was central to the new science of biochemistry, representing, for example, a major focus in Gowland Hopkins' department in Cambridge under the leadership of Marjory Stephenson (1885–1948).

Interest in animal and plant nutrition, especially work on growth factors and vitamins, was extended to microbes in the 1920s and 1930s. In Paris, André Lwoff (1902–94), for example, investigated the growth requirements of protozoa, while in England, Stephenson, B. C. J. G. Knight (1904–81) and Paul Fildes (1882–1971) studied bacterial growth requirements, and in America, Edward Tatum (1909–75) turned to fungal biochemistry. These kinds of investigations led to the concepts of essential nutrients and specific metabolic reactions in microbes.

Microbial Genetics

When George Beadle (1903–89) and Tatum were investigating the genes for eye color in the fruit fly (*Drosophila melanogaster*), they saw an opportunity to examine the biochemistry of gene action in a more tractable system, the biosynthesis of vitamins in fungi. In 1941 they produced pyridoxine-requiring mutants of *Neurospora crassa* by X-ray mutagenesis, and showed that these mutants behaved in a Mendelian fashion in mating experiments. This result suggested to Beadle and Tatum that genes were more or less directly involved in the control of metabolic steps, that is of enzymes. While the exact chemical nature of the gene was unclear at the time (many scientists thought that the genes were the enzymes themselves), they formulated a theory of the gene that came to be known as the 'one gene:one enzyme hypothesis', a basic principle of modern molecular genetics (notwithstanding the additional complexities introduced later by discovery of messenger RNA, splicing, operons, and oligomeric enzymes). This approach, employing both genetic and biochemical studies, was remarkably fruitful and in a few years the notion that genes controlled all the biochemical pathways in cells was widely (although not universally) accepted.

While some of the literature on cyclogeny (a theory based on bacterial growth cycles) suggested that mating, with the formation of zygotic pairs, might occur in bacteria, and some data were presented to support this concept, none of these studies led to new understanding and further progress in the genetics of bacteria. However, after the successful discovery of nutritional mutants in *Neurospora*, C. H. Gray and Tatum in 1944 were able to produce nutritional mutants in bacteria, and in 1947, Joshua Lederberg (1925–) and Tatum carried out experiments with two nutritionally defective mutants of the K-12 strain of *E. coli* (a clinical isolate that had been used in the student laboratory at Stanford University where Tatum had recently taught), and they found that they could obtain recombinant forms of *E. coli* K-12 in a clear demonstration of sexual mating in bacteria. By means of bacterial recombination, a genetic map of *E. coli* K-12 was constructed and by 1952 William Hayes (1913–94) clarified this process of conjugation by his explanation of unidirectional transfer of genetic material. Lederberg and Cavalli formulated bacterial mating as a rudimentary form of sexuality with the donor cell called F+ (fertility plus, 'male'), the recipient called F- (fertility minus, 'female'), and the recipient cell with the donated genes called the zygote. The transfer of the genetic material from donor cell to recipient cell could be interrupted by mechanical agitation of the culture, and François Jacob (1920–) and Élie Wollman (1917–) were able to investigate the nature and sequence of the gene transfer by this 'interrupted mating' ('coitus interruptus') experiment. Since some of the genes they studied did not seem to be associated with the bulk of the cell genes, they hypothesized that some genes exist on extrachromosomal elements, not always present in all cells, which they termed 'episomes' (1958).

While the understanding of microbial genetic processes was increasing during the 1940s and 1950s, the understanding of the nature of the gene itself and of the processes involved in gene stability and change, that is mutation, were also maturing, but from a somewhat different tradition. By the mid-1920s, two strands of investigation converged to direct attention to the problem of heredity in microbes. First, many studies on the virulence of bacterial isolates suggested, even from the time of Pasteur's work on attenuation of virulence, that supposedly pure strains of bacteria could give rise to variants with altered virulence. Second, many bacteria with recognizable colony morphologies, for example, smooth or rough colonies, pigmented or nonpigmented, were noted

to throw off variants of the other type now and then. This phenomenon in which a 'pure' culture 'dissociated' into a mixture of two types was called 'bacterial dissociation' and was widely studied.

Interestingly, explanations of dissociation first centered on the ideas that cultures had 'life cycles' and that the different forms of bacteria represented stages in the life cycle of the culture. Contemporary work on sporulation, protozoal development, 'phase variation' in some bacteria such as *Salmonella*, and fungal growth variations all supported this concept of bacterial 'cyclogeny' as it was termed. The theory of cyclogeny led to a resurgence of the pleomorphism concept of the nineteenth century and was a rather widely held belief in the period between World War I and World War II. The more recent success in the alternative explanation, genetic variation, has all but obliterated memory of the heyday of cyclogeny.

While some bacteriologists, such as Paul Henry DeKruif (1890–1971), better known as a science writer and the author of *Microbe Hunters*, advocated genetic mutation of individual cells as the explanation for bacterial dissociation, the continued focus on the entire culture rather than the individual cell obscured the genetic basis for this phenomenon. Indeed, the genetic status of bacteria and some other microorganisms was unclear. The science of genetics arose from breeding experiments, both in plants and in animals, and its focus was on reassortment and sexual transmission of characters from parent to offspring. Without easily visible chromosomes and without a sexual phase of reproduction, bacteria did not fit into the existing genetic paradigms. As late as 1942, the eminent British biologist Julian Huxley (1887–1975) wrote about bacterial heredity: "One guess may be hazarded: that the specificity of their composition is maintained by a purely chemical equilibrium, without any of the mechanical control supposed by the mitotic (and meiotic) arrangements of higher forms." This view was no doubt strongly influenced by Huxley's contact with Cyril Hinshelwood (1897–1967) and his school which saw bacterial physiology and genetics in terms of chemical kinetics, and which minimized the centrality of the gene in the life of the bacterium.

Perhaps because of the well-known phenomena of adaptation and 'training' of bacteria to different growth conditions, much of the discussion of mutation in bacteria during the 1930s and early 1940s has a strong neo-Lamarckian quality: the exposure of the organism to the agent somehow provoked the observed changes. Exposure of bacteria to bacteriophage led to the emergence of cultures resistant to the phage and often displaying new properties such as altered virulence, changed colony morphology, and different antigenic types. The 'adaptation' of cultures upon exposure to antiseptics, drugs, extremes of pH, and so on, were often seen as purposeful and directed responses.

A minority view in the 1930s was, however, that the dissociation phenomenon was happening independently of the exposure to the agent used to detect the change, that is the phage, drug, or chemical. The major problem in this work was one of experimental design: how to observe a rare event that happened in a huge population prior to the selection for the outcome of that event? In a particularly clear and convincing work, Isaac M. Lewis (1873–1943) examined the mutational change from the inability to ferment lactose to the ability to use this sugar source in the *E. coli* strain *mutabile* (in 1907 Rudolf Massini (1880–1955) reported on a variant of *Bacterium coli* (*E. coli*), which had lost its ability to utilize lactose but which frequently regained this ability and called it *B. coli mutabile*). Lewis spread the parental (lactose-negative) bacteria on glucose-containing plates and also on lactose-containing plates. About one in a million of the bacteria grew on the lactose-containing plates and when retested, all the cells in these lactose-utilizing colonies bred true and could use lactose. By laboriously picking colonies from the glucose plates and testing them for their ability to utilize lactose, he estimated the frequency of lactoseusing bacteria in the culture in the absence of exposure to lactose. This frequency was similar to that determined by plating of the mass culture on lactose medium, so he concluded that the mutations to lactose utilization occurred prior to the selection, not as a consequence of exposure to the selective conditions. This elegant and clear approach, however, did not change many minds, and it was not until the 1940s that two related experimental approaches gave results that comprise the canonical account of bacterial mutation.

In their work on the reproduction of bacteriophage, Max Delbrück and Salvador Luria were aware that bacteria often developed resistance to phage. If a bacterial culture was infected with phage and lysed, sometime later a 'secondary' growth of bacteria would often appear, and these bacteria were resistant to infection with the original phage. While the occurrence of resistant bacteria was a drawback to the use of phage as an antibacterial therapeutic agent, it afforded Luria and Delbrück (1943) an opportunity to study the change in another hereditary property of bacteria. They were also aware of the problem in the interpretation of bacterial mutation experiments. No doubt because of their routine use of statistical models in their work on the inactivation of bacteria and phage by radiation, as well as their backgrounds in atomic physics, they devised a statistical approach to show that phage-resistant mutants exist in the bacterial population prior to exposure to the lethal effects of phage. Their method ('fluctuation test') was based on the properties of the Poisson distribution and the arrangement of the experiment to analyze the frequency of occurrence of mutants in numerous replicate cultures of bacteria. If the occurrence of the mutants took place prior to the analysis (i.e., prior to the application of selective conditions), the Poisson distribution predicted that the frequencies of mutants would fluctuate widely among the replicate cultures. Conversely, if all the mutations occurred during the analysis (i.e., induced by the selective conditions), the frequencies of mutants would be very similar among the replicate cultures. The frequencies fluctuate as predicted by the Poisson distribution; however, Luria and Delbrück showed that this fluctuation could be used to estimate the mutation rate, that is, probability of a given type of mutation per cell division.

The method of Luria and Delbrück and a related procedure devised in 1949 by Howard B. Newcome were indirect, mathematical, and subject to suspicion. However, in 1952 Joshua Lederberg and Esther Lederberg (1922–2006) devised a simple and direct method to demonstrate that mutations were occurring in a random way, independent of the selection procedures. They reasoned that the approach of Lewis was logically correct, but that the methods for its execution had to be improved. They devised a method for transferring very large numbers of colonies from one plate to another by the use of velvet cloth as a transfer tool. The tiny fibers that stand out from the velvet acted as small inoculating needles and picked up some bacteria when pressed against the surface of a

culture plate studded with colonies. When the velvet was pressed on a fresh, sterile plate, this plate was inoculated with bacteria in exactly the same pattern as the original plate. Thus, this 'replica plate' could be used to test colonies in great numbers for mutant properties. Lederberg and Lederberg (1952) applied this technique to the study of phage resistance as well as to the streptomycin resistance, and in both cases it was clear that the mutants had appeared before the application of the selective agent.

Although by mid-century it was generally recognized that bacteria have some sort of genetic apparatus, since they do not have cytologically visible nuclei and chromosomes, the exact organization of the genes was unclear. Perhaps influenced by the widespread interest in cytoplasmic inheritance in higher organisms, there was much discussion about the possibility that bacterial heredity was carried on plasmagenes or that bacteriophage were 'raw genes' from bacteria. Joshua Lederberg (1952) introduced the term 'plasmid' to explain and encompass the wide variety of genetic determinants, which had been observed or hypothesized to exist in microbes. Thus, examples of cytoplasmic inheritance in protozoa, lysogeny in phage, and sometime later, bacterial fertility factors, came under this rubric. This concept, in a variant form described by Jacob and Wollman (1959) under the name of 'episome' nicely explained the genetic studies with fertility factors, specialized transfer of one or a few markers (e.g., the lactose-utilization genes) in some mating experiments, and later on, the 'infectious' nature of antibiotic resistance (resistance transfer factors, RTF) and the variation in virulence and toxin production in many pathogens. Today, the term plasmid has come to signify a circular, extrachromosomal DNA molecule, which autonomously replicates in the cell, and is not essential for that species (although culture conditions, such as the presence of certain nutrients or antibiotics, can make the plasmid essential under specific conditions).

The plasmid concept has facilitated the understanding, too, of the 'gene flow' between the chromosome proper and exogenous agents such as viruses. The ability of some plasmids to undergo genetic recombination with the chromosome explained the mechanisms by which genes can move between species in nature and also established some of the key steps in the process of lysogeny of bacteria by certain bacteriophage. As such, the plasmid concept has been important in understanding the genetics of cancer, as well as certain schemes for evolution of microbes. Of course, the role of plasmids as vectors for gene transfer in current biotechnology is too well known to need elaboration here.

Bacterial Transformation and DNA

With the beginning of the understanding of the process of bacterial mutation as well as the discovery of ways of manipulation of bacterial genes by conjugation, the field of microbial genetics entered the modern period. Two disparate strands of research led to the current understanding of the nature of genes in bacteria. One strand comes from work on bacterial virulence and pathogenesis in pneumonia, and led to the identification of DNA and the chemical stuff of which genes are composed. The other strand comes from the study of bacteriophage replication.

In 1928, Frederick Griffith (1877–1941) was investigating the virulence of the organism that is responsible for pneumonia (*Streptococcus pneumoniae* or 'pneumococcus'), and he found that heat-killed bacteria of one form of pneumococcus could somehow convert live bacteria of another form to exhibit some of the antigenic and virulence properties of the heat-killed form. While these results were of no apparent interest or relevance to the few bacteriologists interested in microbial heredity, they were of real importance to the pathologists interested in pneumonia. Oswald T. Avery (1877–1955), working at the Rockefeller Institute, was one of several scientists who confirmed and followed up Griffith's work with a research program on what he called 'transformation' of antigenic types. Work in his laboratory, first by Martin Dawson followed by James L. Alloway, and then by Colin MacLeod (1909–72) and Maclyn McCarty (1911–2005), eventually led to characterization of the transforming material from the heat-killed bacteria as DNA itself. The final characterization, published in 1944, relied on the use of the newly purified and characterized enzymes, DNase and RNase, as well as several well-known proteolytic digestive enzymes. Still, appreciation of DNA was not universal: at the mid-century meeting of the Genetics Society of America, DNA was hardly mentioned.

Because proteins exhibited the diversity expected of genes and the chemistry of DNA as it was then understood suggested its 'information content' was too low to have genetic potential, DNA was not taken seriously as the genetic material. Two major works soon challenged that belief: using new analytical methods resulting from wartime research, Rollin D. Hotchkiss (1911–2004) showed that the base compositions of DNAs from different organism were not identical and Erwin Chargaff (1905–2002) noted certain regularities in the analyses of all DNAs: the number of purines always equal the number of pyrimidines, and the ratios of adenine to thymine and guanine to cytosine were always very near to one.

While the chemistry of the 'transforming principle' in pneumococcus was being established, a second line of work was going on to understand the process of gene duplication. Max Delbrück saw bacterial viruses (bacteriophage) as a simple model for the process of gene replication and he recruited a group of like-minded associates to attack this problem. In the early stages of their work, the American Phage Group (as Gunther Stent has named Delbrück's school) treated the host bacterium more or less as a 'black box' and studied phage replication as a simple input–output process. In a widely cited experiment, in 1952 Alfred Hershey (1908–97) and Martha Chase (1927–2003) labeled bacteriophage with two isotopes, ^{32}P in the DNA, and ^{35}S in the protein, and in an attempt to follow the fate of the two major components of the phage through one life cycle, they noted that most of the ^{32}P label entered the cell and a significant fraction ended up in progeny phage, while very little of the ^{35}S label entered the cell and even less ended up in the progeny phage. While this result is often described in texts and reviews as if the results were 'all or none', the experimental results given in the original paper, while certainly supportive of the 'only DNA' hypothesis, are far from conclusive.

Another member of the American Phage Group was James D. Watson (1928–), a student of Luria in Indiana University. Watson's thesis was on the radiobiology of bacteriophage and he firmly believed that DNA was the chemical substance of the gene. Watson

and Francis Crick (1916–2004), working at the Cavendish Laboratory in Cambridge England, devised a plausible model for the three-dimensional structure of DNA, which finally provided the much-needed explanatory framework for the genetic role of DNA (1952). Accounts of this landmark research abound, and do not need repetition here.

Physiological Genetics

While the understanding of the role of the gene in the hereditary transmission of properties from parent to progeny organisms and in the explanation of the mutational process derived from research in diverse areas of microbiology as pneumonia research, microbial growth factors, and bacteriophage reproduction, the role of the gene in the growth, development, and physiology of microorganisms was studied in different contexts.

Although as early as Pasteur microbiologists investigated microbial physiology, this field developed rapidly in the 1930s. In parallel with the general advances in biochemical understanding, microbial physiology was important in the discovery of growth factors, in understanding the complexities of nutrition in animals with symbiotic flora (e.g., ruminants), and in appreciating the role of bacteria in conversion of atmospheric nitrogen to organic forms of nitrogen in the process of 'nitrogen fixation' that occurs in the bacteria-packed root nodules of leguminous plants.

A particularly interesting problem in bacterial physiology, one that represented a general phenomenon in microbes, was that of 'enzymatic adaptation'. It was widely observed that cultures growing on one substrate (e.g., glucose) and then shifted to another substrate (e.g., lactose) exhibited a short lag in growth and then 'adapted' to the new substrate by the appearance of an enzyme (or several enzymes), which function to metabolize the new substrate (e.g., lactose-splitting enzymes). The mechanism by which the adaptation occurred was subject of intense discussion and debate up to the mid-1950s. By that time, the work of Jacques Monod and colleagues at the Pasteur Institute had focused on the specific case of the response of *E. coli* to the shifts between glucose and lactose as the sole carbon source for growth. Their early approach was classically physiological, that is, they studied the rates of growth, the kinetics of the adaptations, the levels of the relevant enzymes, and the concentration of substrates involved. A key question arose: when the enzyme appeared in the adaptation (termed 'enzyme induction'), was it made *de novo*, perhaps upon the 'instruction' of the inducer (lactose), or did the enzyme exist in a preformed state, which was somehow stabilized or activated by the inducer? These basically physiological questions were brilliantly reformulated by the group at the Pasteur Institute into genetic terms by the reconceptualization of the process as involving an intermediate system for synthesis of the enzyme, which was distinct from the enzyme itself, and by exploiting mutations affecting the induction phenomenon to identify the components in this hypothetical enzyme-forming system. This work resulted in the operon concept of gene function as first described in 1960 by Jacob, Perrin, Sanchez, and Monod and fully elaborated by Jacob and Monod in 1961. This synthesis of physiology and genetics provided a broad explanation of the biology of a bacterium, *E. coli*, yet it unified as well much of the rest of biological thought. It ended the long estrangement between transmission genetics (Morgan and the 'nuclear monopoly') and the Continental embryologists, who viewed genes primarily as the agents directing growth and development, and rejuvenated interest in what is now known as cell biology.

History of Virology

MBA Oldstone, The Scripps Research Institute, La Jolla, CA, USA

The history of virology can be traced as the personalities involved have described their concepts and published their experimental results. Although infections we now know as, e.g., rabies, yellow fever, smallpox, etc. were clinically evident in early human history, the initial isolation of individual viruses and their assignment to specific diseases did not occur until about 1898, 120 years ago, a proverbial drop in the bucket of time. Just one lifetime ago, Peter Medawar, awarded the Nobel Prize in Medicine and Physiology in 1960, defined viruses as a piece of nucleic acid surrounded by bad news.

The early pioneers in virology had a very limited armamentarium on hand to classify or identify viruses as microbial agents. At the time of their initial discoveries, microscopes of sufficient power to see viral agents were not yet invented; cell cultures to grow viruses were unknown, and probes like antibodies or nucleic acids to mark an infectious agent were not available. Further, biophysical apparatuses like centrifuges or acrylamide gels to concentrate or separate viral proteins or nucleic acids did not exist. Eventually, the will for discovery caused such techniques to emerge. Their use not only defined modern virology and its classifications, but as virology developed it also provided insights that created contemporary cell and molecular biology, protein and structure/function study, immunology, epidemiology for infectious disease analysis, and emergence of treatment. A triumph of modern pharmacology is the formulation of vaccines and, recently, antiviral drugs. Vaccines changed the landscape of virology. Devastating infectious diseases like smallpox, which once killed or maimed millions of humans, have been eliminated, whereas others like poliomyelitis, measles, rubella (German measles), yellow fever, mumps, etc. can be well controlled and others, like influenza, managed. Antiviral therapeutics against HIV now markedly lessen the almost universal mortality rate formerly associated with AIDS. Further, viruses cause at least 20% of all cancers, and vaccines now routinely control liver cancers caused by hepatitis B virus as well as uterine, cervical, and penile cancers caused by several papilloma virus strains. Vaccines have provided the greatest punch-per-buck of any therapeutic regimen in medicine.

Now it is possible, in hindsight, to judge how correct or flawed were the initial concepts formed by early and even recent virologists about the diseases and causes they studied. For this article on the history of virology, selected principles and concepts are reviewed, together with the influences on and reasons for their evolution. Detailed descriptions of viruses that did or do cause plagues and their histories can be gleaned from the publications of McNeill (1976), Oldstone (2010), and Waterson and Wilkinson (1978).

The identification of viruses as infectious agents followed on the heels of pioneer work in the mid-1800s by Louis Pasteur and associates. During that period, the laboratory culturing process was developed for bacteria, which could be grown on enriched agar preparations or broths and were identifiable when the bacteria were fixed on glass slides, stained, and examined under the microscope. Bacteria were isolated by their retention on filters with specific pore sizes (Figure 1(a)). After their collection on filters, growth on agar and identification, specific bacteria could be linked with individual diseases by using Koch's (Henle-Koch) postulates (Figure 1(a)). It was with this framework that the first viruses were uncovered (Figure 1(b)). In 1898, Dmitri Losifovich Ivanovski (Ivanovski, 1899), in Russia, and Martinus Beijerinck (Beijerinck, 1899), in the Netherlands, demonstrated that the material responsible for a disease of tobacco plants, instead of being retained, passed through the then smallest pore-sized filter used in the Pasteur-Chamberland apparatus without losing infectivity. Thus, the material at the bottom of the filter-containing flask was smaller than bacteria and proved to remain infective when transferred to an uninfected recipient (plant) of the type from which it was first retrieved (Figure 1(b)). Ivanovsky and Beijerinck identified the first virus, a plant virus they named the tobacco mosaic virus. Almost concurrently, Friedrich Loeffler and Paul Frosch (Loeffler and Frosch, 1898), in Germany, utilizing a similar approach, concluded that the agent causing foot-and-mouth disease of cattle also passed through porcelain filters and induced symptoms of disease when inoculated back into healthy cattle (Figure 1(b)). These observations, highly controversial at the time, provided the basis for defining viruses as subcellular entities that caused distinct forms of tissue destruction, which became hallmarks of specific diseases. The uniqueness of this detective work is even more dramatic when one considers that the infectious virus particles were too small to see and could not grow on the culture media available (Table 1). Visualization of viruses awaited the use of electron microscopy in the mid-1930s, and the culturing of living cells necessary for viral replication was not possible until the late 1940s to early 1950s. Figure 1(a) illustrates the beginning of microbiology, and Figure 1(b) illustrates the first viral isolations and lists the conceptual problems such virologists had while proving Koch's postulates. Conceptually, a viral replicating agent was distinguishable from a toxin when dilution of the supernatant material that passed through the Pasteur-Chamberland filter lost potency on injection into the appropriate host (then it was a toxin). In contrast, if the diluted material retained potency after injection, it was a replicating agent. Yet, not all material obtained from an infected source and passed through a Pasteur-Chamberland-like filter followed by transmission of infectious supernatant material proved to be a virus (Figure 1(c)). In this illustration, filter passage-infected material from scrapie-infected sheep caused a similar disease when inoculated back into healthy sheep, the natural host. However, not until the 1980-1990 did research show that this infectious material did not contain nucleic acids but rather that disease was transmitted by the misfolded abnormal prion protein (termed PrPres or PrPsc) from infected sheep (Table 1).

Many viral infections cause acute illnesses. That is, the causative virus enters the body, multiplies in one or more tissues, and spreads locally through the blood, along nerves, or along the respiratory or gut tracts. The incubation period of 2 days to 2 or 3

This article is a reprint of M.B.A. Oldstone, History of Virology, *Reference Module in Biomedical Sciences*, Elsevier, 2014.

Figure 1

weeks is followed by signs and symptoms of disease and local or widespread tissue damage. Viruses can be isolated from the patient's blood (serum or blood cells), secretions or washes for a short time just before and after the appearance of symptoms or from their infected tissues. Afterward, the infected host either recovers from the infection, and is often blessed with lifelong immunity to that virus, or dies during the acute phase of illness. Although the majority of life-threatening and debilitating acute virus infections are now controlled through vaccination, it is worthwhile considering the consequences of acute infections like smallpox, measles, and yellow fever in the prevaccine era. Smallpox, before its eradication in 1980, killed over 300 000 000 persons just in the twentieth century and caused a mortality rate of approximately 33% (reviewed in McNeill, 1976, and Oldstone, 2010). In the sixteenth century, when Native Americans were inadvertently exposed to infectious viruses, often carried by Europeans colonizing the New World, the result was a reduction of the native population in Mexico and Latin America from an estimated 20 million to 2 million. This devastating depopulation came primarily from smallpox and measles infections, since these viruses had never before existed in the New World (Oldstone, 2010). Smallpox has now been eliminated from our planet and measles virus controlled, at least in most developed countries. However, measles virus infection was and remains a serious disease today with approximately one per thousand infected persons developing severe destruction of the central nervous system requiring institutionalization. Yellow fever spread up the Mississippi River, carried by infected passengers incubating the disease as they traveled on riverboat(s), embarking from the Caribbean to New Orleans on 24 July 1878, moving on to Vicksburg a few days later and arriving in Memphis, where the first case occurred by 14 August (reviewed in Oldstone, 2010). At that time, no one knew that the infection was transmitted by the bite of *Anopheles Aedes aegypti* mosquitoes. The mosquito sucks blood from an infected person, then transmits the virus by biting an uninfected susceptible person. At the time of the yellow fever outbreak in Memphis, the city population was approximately 98 000 persons. By the end of the two-month epidemic, 20 000 people had fled Memphis. Of those who stayed, 77% were infected and 70% died. The economic result was the destruction of Memphis as a commercial capital in the American South, to be replaced by Atlanta. As reported in the *New York Herald* newspaper by writer Robert Blakeslee, on assignment from New York City to Memphis to cover the yellow fever epidemic, "The city was almost deserted . . . We had not gone far, however, before the evidence of the terrible condition of things became apparent. The first thing in the shape of a vehicle that I saw was a truck (wagon), loaded with coffins, going around to collect the dead. As this was within four blocks of the depot you may imagine how

Table 1 Selected milestones for and in virology

<i>Date(s)</i>	<i>Virologists/investigators</i>	<i>Discovery</i>
400 BCE	Hippocrates	Greek physician, father of medicine, epidemiologic observations of many viral diseases
1796	E. Jenner	Application of cowpox virus for vaccination against smallpox, inflammation origins of virology and immunology
1846	P. Panum	Immunologic memory (protection) against reinfection (measles). Conceptual basis for vaccine strategy
1857	L. Pasteur, R. Koch	Founding of microbiology
1858	C. Darwin, A. Wallace	Concepts of evolutionary progression, natural selection
1865	G. Mendel	Founding of genetics
1883	E. Metchnikoff, P. Ehrlich	Founding of immunology
1885	L. Pasteur, E. Roux	Development of rabies vaccine
1892–98	D. Ivanovsky, M. Beijerinck	First demonstrations of a filterable plant virus: tobacco mosaic virus
1898	F. Loeffler, P. Frosch	First demonstration of a filterable animal virus: foot-and-mouth disease virus
1900	J. Carroll, J. Lazear, A. Agramonte, W. Reed, C. Finlay, W. Gorgas	First human virus: yellow fever virus, first use of consent form for human clinical investigation, identify mosquito as a transmitting agent, control of virus by elimination of mosquito breeding sites
1904–08	V. Ellermann, O. Bang, H. Vallee, H. Carre	First demonstration of a leukemia-causing virus, retrovirus
1908	C. von Pirquet	First report of virus causing immunosuppression: measles virus
1909	K. Landsteiner, E. Popper	Isolation of poliomyelitis virus
1911	J. Goldberger	Discovery of measles virus
1911	P. Rous	First demonstration of a solid tumor virus: Rous sarcoma virus
1915	F. Twort	Discovery of bacteriophages
1917	F. d'Herelle	Bacteriophages, plaque assay
1919	A. Löwenstein	Discovery of herpes simplex virus
1923–28	A. Carrel, H. Maitland, M. Maitland	Tissue culture of embryo explants and first tissue culture cultivation of virus: Rous virus, vaccinia virus
1928	R. Lancefield, E. Lennette, others	Beginning of viral disease diagnosis
1931	J. Furth	Use of mice as a host for viruses
1931	A. Woodruff, E. Goodpasture	Use of embryonated hen's eggs as a host for viruses
1933	W. Smith, C. Andrewes, P. Laidlaw	Isolation of human influenza virus
1933	R. Shope	Rabbit papillomavirus: first DNA tumor virus
1933	A. Tiselius	Development of electrophoresis
1936	J. Cuillé, P.-L. Chelle	Transmission of scrapie to normal sheep by cell-free material from diseased sheep
1936	P. Rous, J. Beard	Rabbit papillomavirus induces carcinomas in a different species
1936	C. Armstrong, T. Rivers, E. Traub	Discovery of lymphocytic choriomeningitis virus: the first arenavirus
1937–51	M. Theiler and others	Development of 17D strain human yellow fever vaccine: made in animal and embryonic cultures
1939	G. Kausche, P. Ankuch, H. Ruska	First electron micrograph of a virus: tobacco mosaic virus
1939	M. Debbruck, E. Ellis	Identification of the one-step virus growth curve
1941	G. Hirst	Discovery of influenza virus hemagglutination, hemagglutination inhibition test
1941	M. Gregg	Discovery of rubella virus congenital abnormalities
1944	O. Avery, C. MacLeod, M. McCarty	Identification of DNA as the material of inheritance
1945	T. Francis, J. Salk, G. Hirst, F. Davenport, E. Kilbourne, others	Development of inactivated influenza vaccines
1946	W. Stanley, J. Summer, J. Northrop	Preparation of a viral protein in a pure form: tobacco mosaic virus
1948–55	J. Enders, T. Weller, F. Robbins, H. Eagle	Routine use of tissue culture to grow and study viruses, development of optimal media for growing cells
1953	J. Watson, F. Crick, M. Wilkins, R. Franklin	Discovery of the structure of DNA
1953	A. Coons	Development of immunofluorescence
1954	J. Salk, J. Youngner, T. Francis, others	Development of inactive poliomyelitis vaccine
1954	B. Sigurdsson	Development of the concept of slow viruses (maedi-visna virus)
1954	W. Rowe	Role of thymus in immune responses to virus
1954–61	J. Salk, A. Sabin, H. Koprowski, J. Enders, S. Katz, S. Krugman	Development of poliomyelitis virus vaccine, development of measles virus vaccine: made in tissue culture
1956	H. Fraenkel-Conrat, B. Singer	Discovery of the infectivity of viral RNA (tobacco mosaic virus)
1956	M. Smith, W. Rowe, T. Weller	Discovery of cytomegalovirus
1957	A. Isaacs, J. Lindenmann	Discovery of interferon
1957	J. Enders, M. Hilleman, A. Gershon, S. Katz, S. Plotkin, M. Takahashi, others	Development of vaccines against measles, mumps, rubella, hepatitis A, hepatitis B

soon I came to a realizing sense of the desolation. Two blocks further on, coffins were piled on tiers on the sidewalk in front of the undertaker's shop, and we were compelled to walk between them . . . Everyone was thoroughly frightened, a young doctor said to me. 'It takes a man of great moral courage to stay in this place. You talk with a man tonight and tomorrow hear that he is in the grave'' (reviewed in Oldstone, 2010). To those who consider this part as ancient and perhaps nonrelevant contemporary history, it is well to recall that during the 1918–19 influenza epidemic in the USA, over 600 000 people died in less than 2 years. In the city of Philadelphia and some other locales, the supply of coffins ran out causing the dead to be buried in mass graves. As recently as the 1980s–90s, a similar scenario played out in parts of Africa when the AIDS epidemic caused by HIV resulted in widely publicized mass deaths and still do in parts of Africa and Asia.

Now these and many other acute virus infections are controlled by vaccination or antivirals and public health policies when and where they are instituted.

Distinct from those acute infections are persistent infections, a major health problem today. In persistent infection, the immune response fails to completely remove viruses from the body, and those viruses remaining then persist in their host for months or years. For infections like those by hepatitis B and C viruses and HIV, viruses can be recovered from the patients' blood for years, during the long course of infection. Although all components (antibodies and T cells) of the immune response are generated during those infections, the T cell response is compromised (by exhaustion or hyporesponsiveness) and is not capable of eliminating the infectious agent.

Table 1 lists events that have impacted the science of virology and its influence on not only diseases but also on the larger milieu of basic research. A more extensive list of important events, observations, and highlights in the discipline of virology has been compiled by Fred Murphy, a long-time contributor to the field, and is accessible at <http://www.utmb.edu/virusimages/>

Introduction

The retroviruses (Retroviridae) comprise a unique and fascinating family of RNA viruses found throughout vertebrate life, characterized by the two defining features of their life cycle: reverse transcription and integration. The process of reverse transcription, where the viral genomic RNA is reverse-transcribed to genomic DNA by the enzyme reverse transcriptase, was believed to be impossible prior to the discovery of retroviruses. While reverse transcription has since been described in other viruses, such as hepadnaviruses and caulimoviruses, the discovery of reverse transcriptase in retroviruses fundamentally transformed the field of microbiology. Integration of the viral genome into the host cell DNA is unique to retroviruses and endows them with the capacity to establish persistent infections and, if a germline cell becomes infected, permanently alter the host genome and achieve vertical transmission as an endogenous retrovirus. Integration into the host genome implies the possibility of altering host cell gene expression, as is the case with oncogenic activation and tumor formation observed in some retroviruses, but also makes retroviruses a promising vector for gene therapy, with the capacity to permanently introduce desirable transgenes. In this chapter, we will discuss

the classification of retroviruses, the structure of these viruses and their life cycle, as well as their capacity to cause disease and their promise as gene therapy vectors.

Taxonomy and Classification

All retroviruses share three genes that are essential to the viral life cycle: *gag*, *pol*, and *env*. *Gag* encodes the structural proteins required for virion formation, *pol* encodes the viral enzymes, and *env* encodes the transmembrane envelope protein, which mediates receptor binding and entry into the target cell. Retroviruses share a common genomic organization, in which *Gag* and a *Gag-Pol* polyprotein are generated via various mechanisms from the full-length genomic RNA (gRNA), and *Env* is produced from a singly-spliced subgenomic RNA. The viral protease (Pro), an enzyme required for viral particle maturation and infectivity, is often referred to as part of the *pol* gene, although it can be produced from a separate open reading frame (ORF) from *pol*, or as part of *gag*. Retroviruses encoding only *gag*, *pol*, and *env* are considered simple retroviruses, while those that encode additional genes are known as complex retroviruses. The retrovirus family is divided into two subfamilies: orthoretrovirinae, which is further divided into six genera, and spumaretrovirinae, which includes only the spumavirus genus (Table 1).

Orthoretrovirinae

Alpharetroviruses

Alpharetroviruses are simple retroviruses in which Pro is encoded in the *gag* ORF, and Pol is produced by a ribosomal frameshift. The virus particle assembles at the plasma membrane and has a central, symmetrically-placed, spherical core (C-type morphology). The genome is approximately 7.2 kb in size, and the Avian leukosis virus (ALV) and Rous sarcoma virus (RSV) are members of this genus. Alpharetroviruses are known to cause malignancies, and many oncogene-containing acute transforming retroviruses belong to this genus.

Betaretroviruses

Betaretroviruses were originally classified as simple retroviruses, but some, such as mouse mammary tumor virus (MMTV), encode the Rem protein, which facilitates gRNA nuclear export. *Gag*, *pro*, and *pol* are each encoded in a different ORF, with Pro and Pol produced following two independent ribosomal frameshift events. The virions of betaretroviruses assemble in the cytoplasm before budding from the plasma membrane, and some members have a round, eccentric core while others have a cylindrical core. The genome is approximately 8–10 kb in length, and other members of the genus include Jaagsiekte sheep retrovirus and Mason-Pfizer monkey virus (MPMV).

Gammaretroviruses

Gammaretroviruses are simple retroviruses which encode *gag*, *pro* and *pol* in the same ORF. Production of the *Gag-Pro-Pol* polyprotein requires translational readthrough of a stop codon at the end of *gag*. Gammaretroviruses, which include the murine

Table 1 Common retroviruses from each genus

<i>Genus</i>	<i>Species</i>	<i>Abbreviation</i>
Alpharetrovirus	avian leukosis virus	ALV
	Rous sarcoma virus	RSV
	Avian myelocytomatosis virus 29	MC29
Betaretrovirus	Mouse mammary tumor virus	MMTV
	Jaagsiekte sheep retrovirus	JSRV
	Mason-Pfizer monkey virus	MPMV
Gammaretrovirus	Murine leukemia virus	MLV
	Feline leukemia virus	FeLV
Deltaretrovirus	Human T lymphotropic virus	HTLV
	Bovine leukemia virus	BLV
Epsilonretrovirus	Walleye dermal sarcoma virus	WDSV
	Snakehead retrovirus	SnRV
Lentivirus	Human immunodeficiency virus type 1	HIV-1
	Human immunodeficiency virus type 2	HIV-2
	Simian immunodeficiency virus	SIV
	Feline immunodeficiency virus	FIV
	Caprine arthritis encephalitis virus	CAEV
	Maedi-visna virus	MV
Spumavirus	Simian foamy virus	SFV
	Bovine foamy virus	BFV

and feline leukemia viruses (MLV and FLV), have a C-type morphology and a genome of approximately 8.3 kb, and they cannot infect dividing cells. Viruses from this genus can cause malignancies, immunosuppression, neurological disorders, and many oncogene-containing acute transforming retroviruses belong to this genus.

Deltaretroviruses

Deltaretroviruses are complex retroviruses with *gag*, *pro*, and *pol* encoded in three distinct ORFs, requiring two successive ribosomal frameshifts to produce the Gag-Pro-Pol polyprotein. These viruses also encode two additional proteins, Rex and Tax, from an alternatively-spliced subgenomic RNA. The genome is approximately 8.3 kb in length, and the virion assembles with a C-type morphology. This genus includes human T lymphotropic virus 1, 2 and 3 (HTLV-1, HTLV-2, and HTLV-3) and bovine leukemia virus (BLV), and does not include any known endogenous retrovirus members.

Epsilonretroviruses

Epsilonretroviruses are complex retroviruses encoding *gag*, *pro*, and *pol* in a single ORF, with production of the Gag-Pro-Pol polyprotein requiring translational readthrough of a stop codon at the end of *gag*. These viruses also include three additional ORFs, termed ORF A, B, and C. ORF A encodes a homolog of the host Cyclin D protein, and the functions of ORFs B and C are unknown. The viral genome is 11.7–12.8 kb in length, and the virion assembles with a C-type morphology. Epsilonretroviruses are exogenous viruses of fish and reptiles, including walleye dermal sarcoma virus and snakehead retrovirus, and some epsilon-like endogenous retrovirus fragments have been described. This genus remains poorly understood, and further investigation may warrant its division into two or more separate genera.

Lentiviruses

Lentiviruses are complex retroviruses encoding *gag* in one ORF and *pro-pol* in another. Production of the Gag-Pro-Pol polyprotein requires a ribosomal frameshift at the end of *gag*. Lentivirus particles assemble at the cell membrane and have distinctive conical cores, and the viral genome is approximately 9.3 kb in length. Lentiviruses include HIV-1 and HIV-2, SIV, caprine arthritis encephalitis virus, and visna virus. They encode several additional proteins, which vary among members of the genus. Lentiviruses are capable of infecting nondividing cells, and are named for the characteristically slow onset of the associated disease. HIV-1 and HIV-2 are the etiologic agents of acquired immunodeficiency syndrome (AIDS) and are the retroviruses responsible for the greatest disease burden in humans.

Spumaretrovirinae

Spumaviruses

Spumaviruses are the only genus of the subfamily spumaretrovirinae and are distinct from orthoretroviruses in many ways, including two defining characteristics: Pro-Pol is expressed from a singly-spliced subgenomic RNA instead of as a polyprotein with Gag from the full-length genomic RNA, and there is a significant amount of reverse-transcribed DNA present in the mature virion. Spumaviruses are complex retroviruses, as they also encode two additional proteins: Tas/Bel-1, a transcriptional transactivator, and Bet. Both Tas/Bel-1 and Bet are produced from RNAs transcribed from an internal promoter within the *env* gene, which further distinguishes spumaviruses from orthoretroviruses. They assemble in the cytoplasm, budding into the ER or at the plasma membrane, and have a unique morphology with an uncondensed core and conspicuous spikes. Gag is processed by Pro to a lesser extent than in the orthoretroviruses, with only a single cleavage occurring near the C-terminus. The genome is approximately 11.6 kb in length, and the genus includes the simian, bovine, equine, and feline foamy viruses, named for the drastic cytopathological changes they cause in vitro. Spumaviruses are not associated with any disease, and while rare infection of humans with simian foamy virus has been observed, no human-human transmission is known to have occurred.

Structure and Composition

Genomic RNA and Protein Nomenclature

The retroviral genome is packaged into viral particles as a dimer of single-stranded, positive-sense, linear RNA molecules. The genomic RNA (gRNA) is produced by the host RNA polymerase II (Pol II) machinery and processed as a host mRNA, with addition of a 5' methyl cap and a 3' poly-A tail. The gRNA includes many important regulatory sequences, shown in Fig. 1. The coding region encodes the Gag, Pol, and Env polyproteins, which are further processed to produce the functional products listed in Table 2.

Structure of Virions

Retroviral virions are initially assembled when unprocessed Gag and Gag-Pol precursors multimerize within the cytoplasm or at the plasma membrane, which is likely mediated by initial interactions between Gag and dimerized gRNA. The immature virion is spherical and appears translucent by electron microscopy. The virion matures when the viral protease (Pro) cleaves Gag and Gag-Pol to the functional products listed above. The mature virion is roughly spherical, but the cleaved CA forms a more ordered viral core around the highly condensed gRNA, which is coated with NC. The viral particle typically contains 1500–2000 Gag precursors, with

Fig. 1 Diagram of the retroviral Genomic RNA (gRNA) highlighting important features. The components of the gRNA are shown from 5' to 3'. A 5' methyl cap is present, as with all host mRNA molecules. R is the repeated sequence found at both ends of the gRNA. U5 is the unique 5' sequence containing an "att" site for integration. PBS is the primer binding site, an 18 nucleotide tRNA hybridization sequence which is complementary to the tRNA primer that initiates reverse transcription. The Psi element (Ψ) is the encapsidation signal for packaging of the gRNA. Gag, pol, and env are the coding regions of the retroviral proteins, and complex retroviruses have additional coding regions in this section of the genome. Ppt is the polypurine tract, the initiation site for plus-strand DNA synthesis. U3 is the unique 3' sequence containing an "att" site for integration. A 3' poly-A tail is present, as with all host mRNA molecules.

Table 2 Protein products common to all retroviruses

Precursor	Protein	Abbreviation	HIV-1
Gag	Matrix	MA	p17

All retroviruses generate Gag, Pol, and Env precursor proteins, which are then cleaved to generate the functional protein products. These products are named in common for all retroviruses with the shown two-letter abbreviations, and the specific names for HIV-1 are also shown.

5%–10% as much Gag-Pol, although this ratio varies depending on the mechanism by which the Gag-Pol polyprotein is generated. The capsid core is made up of primarily hexamers of CA, while some pentamers stabilize the structure. The capsid core is surrounded by a sphere of MA proteins, which is surrounded by a lipid bilayer envelope acquired during budding from the host cell membrane. The lipid envelope includes host transmembrane proteins as well as the heavily glycosylated viral SU and TM proteins, which exist as trimers. SU is entirely extracellular, but remains associated with the envelope through interactions with the single-pass transmembrane TM protein. The number of Env trimers varies among retroviruses, with Gammaretroviruses having as many as 400, while lentiviruses have as few as 2–10. (Fig. 2).

Life Cycle

See Fig. 3.

Receptor Binding and Membrane Fusion

The retroviral life cycle begins when SU trimers on the outside of the virion envelope bind with high specificity to a protein or proteins on the surface of the target cell, which act as the viral receptor. Many different host proteins can act as the viral receptor, although viruses of the same genus often use the same or similar proteins. Receptor usage is determined by the structure of the SU protein, and thus SU is responsible for defining the range of host cells that are susceptible to infection. The SU protein of HIV (gp120) binds to the viral receptor CD4, as well as one of two coreceptors, either CXCR4 or CCR5. As CD4 is predominantly expressed on a subset of T cells, as well as to a lesser extent on macrophages and hematopoietic progenitor cells, these cells represent the primary targets of HIV infection. Upon receptor binding, the SU-TM trimers undergo a structural change that exposes the N-terminal fusion peptide of TM. TM mediates fusion of the viral envelope with the target cell plasma membrane, and the viral core is released into the target cell cytoplasm.

Internalization and Capsid Core Disassembly

The initial stages following membrane fusion and internalization of the capsid core are poorly understood. Most retroviruses do not depend on endosomal acidification to complete this process, although there is evidence that MLV and some alpharetroviruses may require acidic endolysosomal pH for entry. After internalization, it remains unclear precisely what must take place with the capsid core, made up of CA hexamers and pentamers, for productive infection. Maturation of Gag precursors is essential for reverse

Fig. 2 Diagram of the mature retroviral virion. The essential components of mature retroviral virions are depicted, with the protein products labeled in groups according to their unprocessed precursor proteins, Gag, Pol, and Env.

transcription to proceed, and mutations that destabilize or hyperstabilize the capsid core severely hinder reverse transcription. The capsid core may also play a role in shielding the cytoplasmic viral DNA from recognition by innate immune sensors. Recently, it has been described that CA can be detected in the nucleus, suggesting that some amount of CA remains associated with the viral genome throughout the reverse transcription process. Furthermore, CA is the major determinant that allows HIV-1 and other lentiviruses to infect nondividing cells, and many interactions between nuclear import machinery and domains of CA that are only present when it is assembled in the capsid core are essential for this to occur. Thus, it is likely that some remodeling of the capsid core is required for reverse transcription to proceed, without complete disassociation of CA from the reverse transcription complex (RTC).

Reverse Transcription

Upon entry into the target cell, the virus must complete the reverse transcription of its RNA genome into a double-stranded DNA genome, allowing the virus to integrate into the host cell DNA and generate new viral progeny. Reverse transcription is a complex but remarkable process, proceeding through a series of essential steps facilitated by the reverse transcriptase (RT) enzyme that ultimately produces the reverse transcribed complementary DNA (cDNA). Reverse transcription begins shortly after the viral core enters the cytoplasm, although the precise signals regulating the initiation of reverse transcription are unknown, and proceeds within the reverse transcription complex (RTC). The RTC is likely enclosed in a partially-assembled capsid core containing the gRNA dimer and 50–100 RT enzymes. Unlike the orthoretroviruses, spumaviruses undergo reverse transcription during the late stages of infection in the producer cell (Fig. 4).

Initiation of minus-strand DNA synthesis

Reverse transcription begins when the 3'-terminal 18 nucleotides of the primer tRNA hybridize with complementarity to the 18-nucleotide pbs near the 5' end of the gRNA. Each virus uses a preferred tRNA molecule as the primer, which vary among the different retroviruses. The 3'-OH of the tRNA serves as the primer for the initial DNA synthesis, which proceeds toward the 5' end of the gRNA. This generates the U5 and R sequences of the minus-strand DNA, known as the minus-strand strong-stop DNA.

First translocation

The RNase H activity of RT degrades the region of the gRNA complementary to the newly-synthesized DNA, which exposes the DNA as a single strand. The R sequence of the minus-strand DNA is translocated and anneals to the 3' r sequence of the gRNA, leaving a 5' overhang of U5 and the tRNA primer. This translocation is facilitated by NC, and can result in annealing to either of the two gRNAs packaged in the virion.

Long minus-strand DNA synthesis

Synthesis of the minus-strand DNA proceeds along the length of the gRNA, beginning with the strong-stop 3'-OH as the primer. Thus, the entire minus-strand DNA copy of the gRNA is generated. As the DNA polymerase activity of RT synthesizes the

Fig. 3 Diagram of the retroviral life cycle. The critical stages of the retroviral life cycle within a single host cell are depicted, from the infection of a target cell with a mature virus particle to the production of mature virus particles from the infected cell.

minus-strand DNA, the RNase H activity of RT degrades the gRNA from the RNA-DNA hybrid that is generated. This can be performed by the same RT enzyme that is synthesizing the DNA, with degradation occurring 17–18 base pairs behind the elongating 3' end, or by a separate RT enzyme.

Initiation of plus-strand DNA synthesis

In order for synthesis of the DNA plus-strand to begin, a 3'-OH primer is required. The ppt, a purine-rich region of the genome located near the 3' end of the gRNA, is resistant to RNase H degradation and remains intact and bound to the fully-synthesized minus-strand DNA as an RNA-DNA hybrid. The ppt RNA oligonucleotide serves as the primer for initial plus-strand DNA synthesis, which proceeds through U3, R, and U5, continuing up to base 19 of the primer tRNA. The first 18 base pairs of the tRNA are copied, generating the PBS and the plus-strand strong-stop DNA product. The RNase H activity of RT degrades the ppt, which is susceptible to degradation after deoxynucleotides are added. In addition to the ppt near the 3' end of the gRNA, spumaviruses and lentiviruses encode a central polypurine tract that acts as a second primer for plus-strand DNA synthesis, allowing for more efficient production of the plus-strand DNA.

Removal of tRNA and second translocation

The RNase H activity of RT removes the tRNA, exposing the 3' end of the plus-strand DNA, which contains the PBS. The exposed PBS at the 3' end of each DNA strand anneal, generating a circular intermediate with both 3' ends ready for elongation. Each strand serves as the template for the other strand.

(8) Linear product prior to second translocation. (9) Second translocation and formation of circular intermediate with simultaneous minus- and plus-strand synthesis. (10) Completion of minus- and plus-strand synthesis. (11) Finished cDNA product differing from gRNA with the presence of LTRs at both ends.

Completion of both strands

Elongation of the minus strand continues from the PBS through U5-R-U3, displacing the plus strand as it proceeds, creating a ssDNA template for synthesis of the plus-strand 3' LTR. Simultaneously, elongation of the plus strand proceeds along the minus strand from the PBS, through the viral genome, and through the PPT-U3-R-U5 region at the 5' end of the minus strand. Lentiviruses, which

have also initiated plus-strand elongation from a central ppt, generate breaks in the plus-strand DNA with flaps of overlapping sequence. These are eventually corrected by the host cell DNA repair machinery prior to integration.

Upon completion of reverse transcription, it is important to note that the cDNA genome is modified relative to the template gRNA. The overhangs from the two translocations result in the duplication of U5 and U3. The viral DNA now has 2 LTRs, one at each end of the genome, composed of U3-R-U5.

Biochemistry and structure of RT

The amino-terminal domain of RT has DNA polymerase activity, which is unique among DNA polymerases in its ability to use either RNA or DNA as the primer or the template. The DNA polymerase activity of RT is slow relative to host DNA polymerases, ranging from 1 to 100 nucleotide additions per second, with estimates for minus-strand synthesis around 70 nucleotides per minute. It also possesses poor processivity, releasing frequently from the template, and is relatively low-fidelity, generating 10^{-4} – 10^{-5} mutations per base. This low fidelity is exacerbated by the fact that RT lacks any proofreading activity. RT also has a helicase activity that is capable of displacing a DNA strand that is annealed to the template being used, which is essential during synthesis of the minus-strand 5' LTR. The carboxy-terminal domain of RT possesses RNase H activity, which generates oligonucleotides with a 3'-OH, creating a suitable primer from the ppt to initiate plus-strand synthesis. RNase H only degrades RNA in duplex form, either with DNA or RNA, and can act in concert with the DNA polymerase activity of RT.

RT exists as a 75–80 kDa monomer in the gammaretroviruses, which contains both DNA polymerase and RNase H activities. RT forms a heterodimer in the alpharetroviruses, with the alpha subunit containing DNA polymerase and RNase H, and the larger beta subunit also containing integrase (IN). Lentiviruses also produce RT as a heterodimer, which for HIV-1 is composed of a p66 subunit with both DNA polymerase and RNase H, and a p51 subunit, which lacks the RNase H domain but is essential for proper positioning of the p66 subunit for RNase activity.

Recombination between the two copackaged virion gRNAs happens frequently during reverse transcription and contributes to the generation of genetic diversity within the viral population. In order for recombination between the two gRNAs to cause significant changes in the viral genome, the producer cell must be coinfecting with multiple viral genomes. Usually the two gRNAs that are packaged are identical, limiting the effects of recombination events. Recombination is most common during template switching, and is thus a frequent event during minus-strand synthesis, when the template routinely switches back and forth between the two RNA strands. This switching can occur when RNase H degrades the template and allows annealing to the other RNA strand, which may occur more frequently at sites with RNA secondary structures that slow RT DNA polymerase activity, or when nicks in the template strand force a switch to the other strand. Template switching requires that the two gRNAs be similar enough for the 3' end of the growing DNA strand to anneal, and similar enough for the two gRNAs to successfully dimerize and be copackaged into a single virion. Recombination between two gRNAs only occurs between the pairs of a packaged dimer, suggesting that each virion performs its own reverse transcription reaction, and the gRNAs packaged in other virions are not accessible for the duration of reverse transcription.

Nuclear Entry

After reverse transcription has been completed, the RTC transitions to become the preintegration complex (PIC), as the next important step of the viral life cycle is the integration of the double stranded genomic DNA into the host cell genome. The PIC is too large for passive transport across the nuclear envelope, and thus most retroviruses are only able to infect dividing cells after the nuclear envelope has broken down. The lentiviruses, however, can infect nondividing cells by entering the nucleus through the nuclear pore complex (NPC), and this capacity is likely mediated by the lentiviral CA protein, despite previous studies which implicated HIV-1 Vpr, IN, or MA for this function. The spumaviruses are also capable of infecting nondividing cells, although the mechanism is unknown.

Many host proteins are involved in the nuclear import of lentiviruses. NUP358 (RANBP2) is located on the cytoplasmic side of the NPC and interacts with HIV-1 CA to facilitate docking of the PIC at the NPC. NUP153 is located on the nuclear side of the NPC and interacts with residues on CA that are only present when CA is assembled in multimers as in the capsid core, and this interaction is important for HIV-1 integration. TNPO3 also binds CA and facilitates nuclear import of the PIC, and may be involved in removing CA from the PIC once it enters the nucleus. CPSF6 binds CA and is essential for proper trafficking of the PIC to the nucleus and nuclear import, as well as maintaining the characteristic integration site preferences of HIV.

Integration

Integration is the truly unique and defining feature of retroviruses, as it is not an essential function of any other family of viruses. Despite being present in the nucleus, unintegrated retroviral cDNA is a very poor substrate for transcription, and thus an integrated provirus is essential for persistent and efficient expression of retroviral genes. Integration allows retroviruses to occasionally enter the germline and become transmitted vertically, and is also responsible for retroviral-mediated mutational and insertional oncogenesis. Integration is mediated by the IN enzyme, which forms a dimer of dimers structure called the intasome via interactions in the N-terminal oligomerization domain. The catalytic core domain contains three acidic residues that interact with two Mg^{2+} ions, and is highly conserved. The integration reaction proceeds via two steps.

3'-end processing

To initiate the integration reaction, IN recognizes an "A-T-T" sequence at each end of the viral cDNA and removes 2–3 nucleotides (2 for HIV-1) on the 3' strand at each blunt end of the cDNA in a concerted manner, with both ends being trimmed simultaneously. The cleavage occurs at a highly conserved "C-A" sequence in the cDNA, releasing the dinucleotide and leaving C-A-OH 3'-hydroxyl ends. This generates short 5' overhangs at each end of the cDNA.

Strand transfer

After 3' end processing, the target capture complex is formed. The free 3'-OH from the trimmed ends attack the target DNA in a concerted manner, with the two cDNA strands attacking the two strands of the host DNA simultaneously and only a few base pairs apart. This generates two nicks in the host DNA on opposite strands. The two nicks leave an equal number of unpaired complementary bases on either side of the integrated viral DNA, which were annealed to each other prior to the integration reaction. Host DNA polymerase fills in the empty bases on either side of the viral genome, generating a short duplication of the host integration site sequence. The length of the duplication is characteristic for each retrovirus: for instance, 4 bp by MLV and FLV, 5 bp by HIV, and 6 bp by alpharetroviruses. 5' flap endonuclease removes the short 5' overhang generated on the viral DNA during 3' end processing, and DNA ligase seals the gaps to complete the integration of the retroviral provirus. Thus the integrated provirus contains a 2–3 bp deletion from the end of each LTR, as well as a 4–6 bp duplication of the host integration site sequence found immediately adjacent to each LTR.

Integration sites

The integration site has the potential to dramatically affect host cell function by altering gene expression or disrupting functional genomic elements. Integration near oncogenes can cause increases in oncogene expression and drive tumor development. Retroviral integration sites are not sequence-specific, and for the alpharetroviruses and betaretroviruses, the integration site is essentially random through the entire host genome. However, despite the absence of a specific integration site sequence, other retroviruses demonstrate preferential integration into certain locations in the host cell genome. Gammaretroviruses tend to integrate in promoters and DNase 1 hypersensitive regions, which are characteristic of open chromatin and likely enhance the likelihood that the viral genes will be expressed. On the contrary, spumaviruses puzzlingly appear to disfavor integration in genes and sites of active transcription. Lentiviruses, including HIV, preferentially integrate within expressed genes, intron-rich regions, and in chromatin located near the nuclear envelope, while avoiding chromatin in lamina associated domains.

Transcription

The integration of the virus into the host cell DNA, establishing a permanent provirus within the genome of the infected cell, marks the end of the early phase of retrovirus infection, shifting the focus to the production of new virus particles. The first step in virion production is the initiation of transcription from the promoter found within the 5' LTR, which is responsible for producing both the mRNAs needed to encode the viral structural proteins and the gRNA. Initiation of transcription at the 5' LTR is stochastic, although the U3 region contains a promoter, with both a TATA box and CCAAT box, as well as a range of enhancers. U3 enhancer regions recruit several transcription factors, including NFκB, AP-1, NFAT, SP-1, and CBF1, among others. Transcription of the provirus is performed by the host Pol II enzyme and initiates at the U3-R border.

Many complex retroviruses encode additional trans-activating proteins to enhance expression of the viral genes. HTLV encodes Tax, which recruits CREB to three cAMP response elements in the LTR to enhance LTR-driven transcription. HIV encodes Tat for a similar purpose, although Tat functions by binding to the TAR element, a secondary structure near the 5' end of the nascent viral RNA. Tat then recruits P-TEFb, increasing the processivity of Pol II, which tends to stall early in the transcription of the HIV genome, by phosphorylating the Pol II C-terminal domain.

Transcription proceeds through the 5' LTR and the coding region of the viral genes and concludes in the 3' LTR, where transcription stops at the R-U5 border. A 5' methyl cap is added, and the 3' end is poly-adenylated. This generates the full-length viral RNA, which serves as both the packaged gRNA and as the mRNA template for translation of Gag and Gag-Pol polyproteins. In addition to the promoter in the 5' LTR, which is responsible for driving all orthoretrovirus gene expression, the spumaviruses have an additional internal promoter, which drives expression of the proteins Tas and Bet.

Splicing and Nuclear Export

Upon generation of the full-length viral RNA, simple retroviruses require the successful nuclear export of two RNA forms: a singly-spliced variant that is used to produce Env proteins, and the full-length RNA for production of Gag-Pol and packaging into nascent virions. Complex retroviruses include other alternatively-spliced or multiply-spliced subgenomic RNAs. The splicing of the singly-spliced variants uses host cell machinery and behaves similarly to any cellular mRNA. Export of unspliced or incompletely spliced RNA, however, is inefficient, as host nuclear export factors are often recruited during splicing, and splicing factors that bind introns provide signals to prevent nuclear export. Thus, most host RNAs are properly and completely spliced prior to nuclear export.

For simple retroviruses, which encode no proteins in addition to Gag, Pol, and Env, export of the unspliced viral RNA can take advantage of several mechanisms. Many retroviruses, including MPMV, contain sequences called constitutive transport elements

(CTEs), which promote export by directly binding to the host export factor TAP/NXF1. Retroviruses also possess low-efficiency 3' splice sites, which can prevent binding of splicing factors that act as negative regulators of nuclear export of incompletely spliced RNAs. Mutations to improve the efficiency of these splice sites inhibit the replicative fitness of retroviruses. The inefficient splice sites act in concert with negative regulators of splicing (NRS) sequences, which further prevent splice factor binding, to preserve the unspliced, full-length RNA for nuclear export. For RSV, the Gag protein can facilitate nuclear export of the full-length RNA. Gag has nuclear localization signals (NLS) in both the NC and MA domains, which allow Gag to enter the nucleus. The interaction between NC and the Psi element of the viral RNA exposes a nuclear export signal (NES) in the p10 domain of Gag, allowing the Gag-gRNA complex to exit the nucleus.

With the benefit of encoding additional genes, the complex retroviruses have evolved additional methods for promoting the export of partially spliced or unspliced RNA. Splicing of HIV is very complex, with at least four 5' splice donor sites and eight 3' splice acceptor sites. The major splice donor site is used in generating each of the spliced RNA products. Thus, there are many incompletely spliced subgenomic RNAs, as well as the unspliced gRNA, that must be exported. HIV encodes Rev to facilitate this process. Rev binds to a specific element on the viral RNA, the Rev-response element (RRE), and then binds to CRM1, which is responsible for the export of proteins containing a NES. HTLV Rex and MMTV Rem function similarly and for the same purpose.

Translation and Protein Processing

The Gag, Pol, and Env proteins are essential to the production of infectious virions for all retroviruses. Each of these proteins is translated as a precursor that is eventually cleaved and processed into the functional subunits that form a mature virus particle. Producing precursors likely benefits retroviruses in many ways, including producing several functional proteins from a single ORF, guaranteeing that proteins are produced and packaged in the appropriate ratio, and targeting many proteins to the site of virion assembly simultaneously.

Gag

The Gag precursor is produced from the full-length RNA. Some retroviruses employ an internal ribosomal entry site (IRES) near the *gag* start codon to prevent the need for translational initiation at the 5' cap, which requires an elongated scanning through the R-U5 region of the genome. The major form of Gag is myristylated by myristyl CoA transferase, increasing the hydrophobicity of Gag and facilitating membrane association and packaging into the virion.

Pro-Pol

The viral protease is also produced from the full-length RNA and exists between the *gag* and *pol* genes. It can be fused to the 3' end of *gag*, the 5' end of *pol*, or neither, and is often produced along with Pol, which includes RT, IN, and dUTPase (DU) for some retroviruses, by translational readthrough or frameshifting.

Gammaretroviruses and epsilonretroviruses use translational readthrough, as Gag-Pro-Pol is encoded in a single ORF. A UAG stop codon between *gag* and *pro-pol* is translated as glutamine 5%–10% of the time due to the existence of a purine-rich region and pseudoknot structure downstream of the stop codon, which promote ribosomal slippage. This results in the Gag-Pro-Pol polypeptide being 10–20-fold less abundant than Gag, which is needed at higher quantities than the viral enzymes.

Alpharetroviruses and lentiviruses require a single –1 frameshift to occur during the junction between *gag* and *pol*, as they exist in separate ORFs. This is facilitated by a slippery region near the *gag* stop codon, which includes homopolymeric bases such as poly-A or poly-U and a large hairpin, stem-loop, or pseudoknot structure. The –1 frameshift results in an out of frame *gag* stop codon, and translation continues through the *pol* ORF. This occurs in 5%–10% of translation events, resulting in Gag-Pol being 10–20-fold less abundant than Gag. For alpharetroviruses, *pro* is in the *gag* ORF and Pro is produced equimolar to Gag, whereas in lentiviruses *pro* is in the *pol* ORF and Pro is produced equimolar to Pol.

The betaretroviruses and deltaretroviruses require two –1 frameshifts, the first at the end of *gag* to avoid the *gag* stop codon and enter the *pro* ORF, and the second at the end of *pro* to avoid the *pro* stop codon and enter the *pol* ORF. Each of these frameshifts can occur up to 30% of the time, resulting in a decreasing abundance of Gag, Gag-Pro, and Gag-Pro-Pol precursors.

Spumaviruses are unique in their production of the Pro-Pol precursor from a spliced, subgenomic mRNA. Thus, Pro-Pol for spumaviruses is not synthesized as a polypeptide with Gag and must be packaged into the mature virion independent of the Gag packaging signal.

Env

All retroviruses produce the Env precursor from a singly-spliced subgenomic RNA, with a 5' leader sequence joined directly to the *env* coding region after *gag-pol* is removed as an intron. Env is synthesized as a single-pass transmembrane protein in the ER, where it is folded, glycosylated, and oligomerizes to form Env trimers. Unlike the other retroviral precursor proteins, the Env precursor is not processed by the viral protease, but rather by host furin proteases in the Golgi, which separate the SU and TM subunits. SU is wholly extracellular and remains associated with the virion via interactions with TM. It is heavily glycosylated, protecting the virion from neutralizing antibodies by shielding antibody epitopes, and contains hypervariable regions that determine receptor binding. TM has extracellular, transmembrane, and cytoplasmic domains, with the extracellular N-terminus containing the fusion peptide, which is essential for membrane fusion during entry into the target cell. TM also contains the major contacts for oligomerization. Some mannose residues are removed and N-acetyl glucosamine is added in the Golgi, and trimers of SU-TM heterodimers are transported to the cell surface for assembly.

Assembly and Packaging

Assembly of retroviral virions is predominantly mediated by Gag precursors, as these are sufficient for production of virus-like particles in the absence of any other viral factors. The C-type viruses assemble at the plasma membrane, with Gag targeted there by hydrophobic residues, basic residues, and myristic acid. For HIV, the MA domain of Gag, which has a myristic acid added to the N-terminal glycine, embeds in the plasma membrane and forms stable anchors only upon binding to PI(4,5)P₂, which is specifically localized to the plasma membrane. This prevents improper virion assembly at internal membranes. The MA domain of Gag also localizes HIV to budding lipid rafts and incorporates the glycosphingolipid GM3 into the envelope, which is later recognized by CD169/Siglec-1 on dendritic cells (DCs) to enhance trans-infection of CD4⁺ T cells. The Gag proteins aggregate, causing curvature in the plasma membrane and initiation of budding. Some retroviruses, including betaretroviruses, assemble in the cytoplasm. The assembled virions are then transported to the plasma membrane for envelopment and release.

The SU and TM trimers of heterodimers are incorporated via contacts between the cytoplasmic tail of TM and the N-terminus of Gag, although there are likely additional mechanisms involved. HIV incorporates Vpr into virions at a high level, roughly equimolar with Gag. The recruitment of Vpr into virions requires the Gag p6 domain, although the function of Vpr remains unclear. Host proteins are also incorporated into virions, including Cylophilin A, which has many different effects on Gag stabilization and disassembly and can promote or reduce retroviral infectivity depending on the experimental context.

The proper packaging of the gRNA represents a challenge for retroviral assembly, as the gRNA comprises only a small fraction of the total cytoplasmic RNA in the host cell, and many viral subgenomic RNAs are also present and must be excluded from the assembling virion. The gRNA is packaged as a dimer, which is usually a homodimer of two identical gRNAs, except in rare cases where coinfection or expression of an endogenous retrovirus causes packaging of an RNA heterodimer. Packaging is mediated by the Psi (Ψ) sequence in the 5' UTR, which interacts specifically with the NC subunit of the Gag precursor. In the absence of a Psi signal, virions package a random sampling of host mRNAs, and non-gRNAs can be packaged if they are engineered to contain a Psi sequence. HIV-1 splices the Psi sequence out of the subgenomic RNAs to prevent packaging interference with the gRNA. HIV-2 and ALV subgenomic RNAs retain Psi and must regulate packaging by other means. It has been proposed that a Gag precursor protein binds to the gRNA from which it was translated immediately posttranslation, thus ensuring that Gag assembly only occurs around unspliced, Gag-encoding gRNAs. The gRNA binds the Gag precursor protein in different subcellular locations for different retroviruses. MLV and RSV bind Gag in the nucleus, MMTV and MPMV in the pericentriolar region, FIV binds Gag at the nuclear membrane, and HIV-1 binds Gag in the cytoplasm. Gag is then responsible for the trafficking of gRNA to the assembly site for packaging.

Psi functions via cis-acting structural elements of the RNA, including stem loop structures containing purine-rich loops. For HIV-1, stem-loops 1 and 3 (SL1 and SL3) are especially important for packaging. For MLV, the 4 stem loops of Psi are referred to as A-D, where A and B facilitate dimerization of the gRNA, while C and D interact with the NC subunit of Gag precursors to encourage encapsidation.

Dimerization of the genome

Dimerization of the two packaged gRNAs is mediated by interactions in a complementary sequence near the 5' end of the genome called the dimerization initiation site (DIS). For HIV, the DIS is in SL1. The DIS and *gag* start codon are both near the 5' end of the viral RNA and determine whether the RNA dimerizes for packaging as a gRNA or is translated to produce Gag or Gag-Pol proteins. Changes in the secondary structure of this region occur in many retroviruses, allowing either the DIS or the *gag* start codon to be accessible, but not both, distinguishing the gRNA from the mRNA. When the DIS of two gRNAs bind, they form the dimer linkage structure (DLS). The NC subunit of the Gag precursor protein binds the DLS with high specificity, initiating Gag multimerization and assembly. These interactions are more specific than the generic affinity of NC for RNA, ensuring that dimerized gRNAs are packaged. Other domains of the Gag precursor may be involved in this interaction as well. The dimerized gRNAs are noncovalently associated and do not form significant base-pairing interactions, and dimerization is stabilized during virion maturation after release from the producer cell.

The timing of gRNA dimerization varies among the retroviruses. MLV dimerization initiates in the nucleus shortly after transcription, which increases the likelihood that identical gRNAs are copackaged as a homodimer. HIV-1 dimerization, on the other hand, initiates in the cytoplasm, increasing the likelihood that the dimerizing gRNAs will not be identical, and increasing the rate of recombination for HIV-1 up to 10-fold relative to MLV.

Dimerization has several purported benefits for retroviral replication. Nicks in the gRNA are common, and proper completion of reverse transcription would be impossible from a single nicked genome. Copackaging a second copy can greatly increase the fidelity of reverse transcription by increasing the likelihood that an intact template exists for each region of the genome. Dimerization also distinguishes the gRNA from spliced mRNA, as only dimerized gRNA has the DLS as a signal for Gag recruitment and assembly. Furthermore, recombination can drive evolution, as there are approximately 3–10 strand transfers per replication cycle. Retroviruses have higher rates of recombination than other RNA viruses, which may contribute to the adaptability of the virus. As spumaviruses perform reverse transcription prior to packaging, it is unclear whether they require dimerization.

Budding and Maturation

Gag precursors assemble at the plasma membrane, inducing membrane curvature and initiating the budding process. The p6 domain of the HIV-1 Gag precursor recruits the endosomal sorting complexes required for transport (ESCRT) machinery by binding

to TSG101 and ALIX, and the NC domain of Gag may be involved in ESCRT recruitment as well. ESCRT machinery is responsible for release of the immature virion.

Upon virion release, the viral PR enzyme cleaves itself out of its precursor form, which varies depending on the retrovirus. PR acts as a homodimer and subsequently cleaves the remaining Gag and Gag-Pol precursors in hydrophobic regions, triggering a number of events that generate the mature, infectious virion. Prior to PR processing of the precursors, retroviral virions are immature and noninfectious. Thus, mutations to or inhibition of PR can prevent retroviral infection.

Processing of Gag precursor

The MA protein remains bound to the inner face of the membrane via the N-terminal myristyl group. It may interact with TM for proper incorporation of Env trimers into the virion, and is referred to as p17 in HIV-1. The CA protein contains the major homology region and is conserved among all retroviruses. Upon cleavage, CA undergoes a dramatic rearrangement that is visible by electron microscopy, forming the condensed inner capsid core. The shape of the capsid core depends on the individual virus, but it is made up of CA-CA interactions that form primarily hexamers and some pentamers. For HIV-1, the CA protein is called p24. The NC protein is small and highly basic. After release from the Gag precursor, the basic NC coats the entire gRNA, with one NC protein for every 5–8 nucleotides. This is important for successful reverse transcription, as NC likely helps RT to proceed through regions with significant secondary structures, and also facilitates the various strand transfers that take place. NC processing results in pbs remodeling, exposing the 18 nucleotides with perfect complementarity to the 3' end of the primer tRNA and allowing binding of the primer tRNAs to the pbs of each gRNA. This sets the stage for reverse transcription upon infection of a new target cell. For HIV-1, NC is referred to as p7.

Processing of Gag-Pro-Pol precursor

The Gag-Pol precursor is processed by PR into RT, IN, and the Gag subunits described above in all retroviruses, and additionally DU in some retroviruses. The functions and structures of RT and IN have been described above. DU is an enzyme that prevents the incorporation of dUTP during viral DNA synthesis by hydrolyzing dUTP to dUMP, reducing the amount of available dUTP relative to other dNTPs. DU is part of the *pro* ORF for betaretroviruses and the *pol* ORF of the nonprimate lentiviruses. Bovine lentivirus encodes an inactive DU, while the primate lentiviruses do not encode DU.

Host Response to Retroviral Infection

As retroviruses have been circulating in vertebrate genomes throughout evolutionary history, the host species have evolved a number of mechanisms to defend against retroviral infections, involving both innate and adaptive immune responses. Likewise, retroviruses have evolved to counteract these defense mechanisms, which is the role of many of the accessory proteins encoded by the complex retroviruses. This evolutionary race determines the tropism of the retroviruses, as each species is able to prevent infection by all but a few specific viruses that have evolved to overcome these restrictions in a species-specific manner.

Innate Immunity

The APOBEC3 family of host proteins are packaged into retroviral virions in a NC-dependent manner and restrict multiple retroviruses, including HIV and HTLV, by inducing hypermutation. Although APOBEC3G is the most widely-studied, other APOBEC3 family members, including 3B, 3D, 3F, and 3H are also active against HIV. APOBEC3G is a cytidine deaminase that deaminates cytidine nucleotides, generating uracil in the minus-strand ssDNA after RNA degradation but before plus-strand synthesis, resulting in a G-A mutation in the plus-strand DNA. It is expressed at high levels in human CD4⁺ T cells and macrophages, the primary targets of HIV infection. This may explain the presence of the central PPT of HIV-1, which hastens positive-strand synthesis and reduces the exposure of the minus-strand DNA to APOBEC3. Vif, an accessory protein encoded by almost all lentiviruses, counteracts APOBEC3 proteins by inducing their polyubiquitination and proteasomal degradation, preventing their packaging in budding virions.

During reverse transcription, retroviruses generate RNA-DNA, ssDNA, and dsDNA in the cytoplasm of the host cell, none of which are present in the cytoplasm during normal host cell processes. As with other viruses, many sensors of retroviral nucleic acids have been described, including cGAS and IFI16. Cytosolic DNA is detected by cGAS, which interacts with STING to signal the production of interferon- β (IFN- β) via IRF3. HIV evades cGAS, however, by recruiting the host TREX1 protein to degrade viral DNA products that are susceptible to sensing by cGAS. IFI16 also senses cytoplasmic DNA, acting via STING to induce IFN- β . For HIV-1, this pathway may contribute to loss of CD4⁺ T cells and progression to AIDS, as pyroptotic CD4⁺ cell death following abortive HIV-1 infection requires IFI16.

SAMHD1 is a host protein that restricts HTLV and HIV-1 in some cell types, such as DCs, macrophages, and resting CD4⁺ T cells, by depleting the cellular pool of dNTPs needed for cDNA synthesis. With reverse transcription unable to proceed to completion, the intermediates can be recognized by innate immune receptors like cGAS to activate an antiviral response. SAMHD1 is also likely to play a role in preventing retrotransposon activity. HIV-2 and SIV overcome this restriction by encoding the accessory protein Vpx, which recruits the E3 ubiquitin ligase DCAF1-DDB1 to induce degradation of SAMHD1. Vpx is absent in HIV-1, allowing SAMHD1 to reduce HIV-1 infection of SAMHD1-expressing cells, including DCs, resting CD4⁺ T cells and, to a lesser extent, macrophages.

SERINC3 and SERINC5 were recently discovered as membrane-bound restriction factors of HIV-1, which are incorporated into the virion to reduce particle infectivity. HIV-1 counteracts this restriction with the accessory protein Nef, which redirects SERINC3 and SERINC5 away from the cell surface to prevent their incorporation into virions. Nef also facilitates HIV-1 infection in a number of other ways, including redirecting MHC-I to the lysosome for degradation to prevent antigen presentation to CD8⁺ T cells and internalizing CD4 from the cell surface to prevent superinfection and Env interactions with CD4 during virion budding.

The TRIM5 α protein, which was previously called Ref1 and Lv1, binds to the retroviral capsid core and accelerates uncoating in a proteasome-dependent manner, inhibiting reverse transcription and formation of a functional PIC. Trim5 α proteins vary from species to species, and the species-specificity of primate lentiviruses is largely determined by their ability to evade restriction by TRIM5 α in their native host species, but not in other primates. Fv1 is an additional restriction factor found in mice, which targets residues of Gag in gammaretroviruses. The restriction occurs after reverse transcription but before integration.

Tetherin, also known as BST2, tethers budding retroviral virions to the cell surface, preventing virion release and leading to internalization and degradation. HIV-1 overcomes the tetherin restriction with the accessory protein Vpu, which prevents tetherin from reaching the cell surface and leads to its degradation. HIV-2 and SIV do not encode Vpu, but SIV Nef facilitates the AP-2-dependent internalization of tetherin at the cell surface, while the HIV-2 Env protein is sufficient for HIV-2 to overcome tetherin restriction.

Other restriction factors that have recently been described for HIV-1 include MxB/Mx2, which is IFN-inducible and inhibits nuclear import or uncoating, and IFITM1, which is a plasma membrane protein preventing fusion and entry. The specific mechanisms of action for these recently-discovered restriction factors are still being elucidated.

Adaptive Immunity

CD8⁺ T cells represent the primary antiviral effectors of cellular adaptive immunity, and massive HIV-specific CD8⁺ T cell responses are observed shortly after the initial detection of HIV RNA in the plasma. While these responses shape the viral landscape and motivate viral evolution, they are unable to successfully control the infection in most individuals, and fail to clear the virus entirely. These CD8⁺ T cells eventually become exhausted, losing their ability to control the evolution and spread of the virus. HIV-1 and HIV-2 also encode the accessory protein Nef, which removes MHC-I from the surface of infected cells to prevent presentation of viral peptides and recognition by HIV-specific CD8⁺ T cells. A small subset of individuals known as elite controllers naturally suppress HIV-1 viral load and prevent progression to AIDS, and this control is due to their unusually effective CD8⁺ T cell responses.

Humoral immunity to HIV-1 and SIV is also observed, with both neutralizing and nonneutralizing antibodies generated against the virus within the first 2 weeks of infection. The earliest detectable antibodies recognize Gag antigens, followed by those from Nef, Rev, and Env. Neutralizing antibodies predominantly target the HIV-1 Env receptor binding domains: the V1, V2, and V3 loops and the CD4-binding domain of the HIV-1 gp120 (SU). They interfere with the ability of the virus to interact with the receptor and prevent entry into the target cell. As V1, V2, and V3 are hypervariable regions of gp120, the virus rapidly evolves to avoid these neutralizing antibody responses, which fail to control spread and suppress viral loads. Neutralizing antibodies isolated from an infected individual often successfully neutralize previous isolates of virus from that individual, but fail to neutralize the virus that is currently circulating. Nonneutralizing antibodies can mediate antibody-dependent cell cytotoxicity (ADCC) and facilitate killing of infected cells by NK cells and macrophages, although the significance of this mechanism in controlling viral replication remains poorly understood.

Some neutralizing antibodies that have undergone extensive somatic hypermutation following years of exposure to high viral loads have developed the capacity to neutralize a broad range of HIV isolates and are known as broadly neutralizing antibodies. While the existence of broadly neutralizing antibodies offers some promise for HIV-1 vaccine development, various vaccine strategies have failed to elicit these responses.

Retroviral Diseases

Cancer

Retroviruses were first discovered when Rous sarcoma virus (RSV) was identified as the etiologic agent of a sarcoma in chickens, which was also the first established link between a viral infection and cancer. Since then, many cancer-causing retroviruses have been described, which can be divided into two categories: acute transforming retroviruses and nonacute transforming retroviruses.

Acute transforming retroviruses

The acute transforming retroviruses are distinguished by the rapid onset of cancer following viral infection, caused by mutated versions of cellular proto-oncogenes carried in their genomes. These genes usually alter cell cycle regulation or susceptibility to apoptosis, and include growth factors, growth factor receptors, tyrosine kinases, G proteins, transcription factors, and other types of genes. RSV encodes *v-src*, the viral oncogene derived from the cellular proto-oncogene *c-src*, whereas MC29 encodes *v-myc*, derived from *c-myc*. The viral oncogenes can be acquired by different means, but the process usually involves insertion of the retroviral genome upstream or in the middle of the transduced gene. Readthrough transcription can generate a chimeric RNA that is spliced to contain only the exons of the cellular proto-oncogene and is subsequently packaged into the virion. Nonhomologous

recombination during reverse transcription results in the acquisition of the cellular proto-oncogene as a viral oncogene. To accommodate the viral oncogene within the size limitations of retroviral genomes, viral components essential for replication are often lost, and the oncogene is often fused to *gag*, *pol*, or *env*. Despite the fact that many acute transforming retroviruses are replication incompetent on their own, they always retain the necessary cis elements for replication, including LTRs, the pbs, ppt, and Psi sequence. Thus, in the presence of a helper virus, which coinfects the same cell and expresses the essential viral proteins that are lacking, acute transforming retroviruses can be packaged and produce particles capable of single-round infection. In rare circumstances, as with RSV, the viral oncogene can be acquired with no loss of replication competency and no requirement for coinfection with a helper virus.

Nonacute transforming retroviruses

The nonacute transforming retroviruses differ from the acute transforming retroviruses in that they do not encode oncogenes, and thus do not rapidly induce transformation upon infection. Rather, during the course of a persistent infection or multiple infection events, as the virus continues to replicate and integrate proviral genomes into various host cells, random proviral insertional mutagenesis can occur. When the proviral genome integrates near or within a host proto-oncogene or tumor suppressor gene, it can alter the expression or functionality of the gene and ultimately lead to cancer development. There are multiple mechanisms by which this can occur, most often involving the promoters and enhancers in the viral LTR stimulating nearby host cell gene expression in addition to viral gene expression. If the virus integrates immediately upstream of a proto-oncogene, the 3' LTR promoter can help drive expression of the host gene, generating an altered transcript containing the viral R-U5 sequence at the 5' end. Proximal insertion to a proto-oncogene can also result in enhancer insertion, where the LTR enhancers facilitate transcription from an endogenous host promoter, generating the native transcript in higher frequencies. Insertional mutagenesis can also transform cells by altering posttranscriptional modifications of host products, or by readthrough transcription from the 5' LTR, which is most common in mutated proviruses lacking the 3' LTR stop signal. ALV causes lymphoid tumors in chickens after integrating upstream of *c-myc*, while MLV and FeLV cause leukemias following insertion upstream of a number of described genes. MMTV causes mammary carcinomas and integrates in the vicinity of growth factor genes, including *wnt* and *fgf-3*.

AIDS

By far the most significant retroviral disease burden in humans is the acquired immunodeficiency syndrome (AIDS), which is caused by untreated infection with either HIV-1 or HIV-2. AIDS was first recognized in the United States in 1981, a series of investigators from 1983 to 1984 identified that retroviruses may be the cause of AIDS, and by 1986 these retroviruses were identified as HIV, which was subsequently named HIV-1 upon the discovery of HIV-2. HIV-2 has only 45% sequence homology to HIV-1. HIV-2 differs from HIV-1 in that it encodes Vpx, which counteracts SAMHD1. In addition, HIV-2 lacks Vpu, which downregulates tetherin and CD4, and is less pathogenic than HIV-1. HIV-1 is separated into four groups: M, N, O, and P, of which M is responsible for the majority of infections worldwide. Group M is separated into nine subtypes, of which subtype B is most common in Europe and North and South America, while subtype C is by far the most prevalent subtype worldwide. HIV-2 is divided into eight groups, named A-H. Most clinical HIV research is done on HIV-1, group M, subtype B viruses.

HIV is transmitted primarily through sexual contact or exposure to blood, such as during blood transfusions or intravenous drug use. It can also be transmitted perinatally between mother and child during pregnancy, labor, or breastfeeding. During acute infection, some individuals can experience flu-like symptoms. After an initial peak in plasma viremia is established within a few weeks of exposure, immune responses primarily dependent on HIV-specific CD8⁺ T cells begin to control the virus, suppressing the plasma viral load to the viral set point, but failing to completely prevent viral replication or clear the infection.

The virus requires its receptor, CD4 plus a coreceptor, either CCR5 or CXCR4, to enter cells. Thus, the virus replicates primarily in CD4⁺ T cells, which express high levels of CD4. HIV-1 can also infect cells with lower levels of CD4, including macrophages and hematopoietic stem and progenitor cells. Infection of CD4⁺ T cells leads to cell death, and persistent viremia leads to a steadily decreasing CD4⁺ cell count during the course of infection. This depletion occurs gradually during a prolonged asymptomatic phase of infection, which can last for several years. AIDS is associated with a suite of rare opportunistic infections and tumors that are typically suppressed by normal immune responses, and these opportunistic infections and tumors are responsible for most AIDS-related deaths.

In addition to infecting CD4-expressing cells, HIV infection can affect other cell types as well. CD8⁺ T cells and B cells can both be killed by bystander activation. While dendritic cells (DCs) aren't productively infected by HIV-1, as they express high levels of SAMHD1 to restrict the infection, they are susceptible to infection by HIV-2 and SIV, which encode Vpx to counteract SAMHD1. In the context of HIV-1, DCs can still contribute to infection through trans-infection of T cells, in which DCs capture viral particles, maintain their infectivity, and transfer them to T cells at the virological synapse. Initial studies implicated DC-SIGN and similar receptors as essential for trans-infection via DCs, although recent studies have shown that GM3 incorporated in the HIV-1 envelope is recognized by CD169/Siglec-1 to facilitate trans-infection. DCs can also produce interferon during acute infection, and are especially sensitive to HIV-2, where DC infection proceeds sufficiently for cGAS recognition of viral DNA.

Throughout the world, and even within a single individual, HIV demonstrates tremendous genetic diversity. This genetic diversity allows the virus to rapidly evolve to evade host adaptive immune responses, as well as antiretroviral monotherapies. The RT enzyme has a particularly low fidelity among DNA polymerases, which is likely the major contributor to HIV mutagenesis. HIV is especially variable in the exposed regions of the envelope protein. This variability likely benefits the virus in evading the host humoral response, which is directed predominantly against exposed residues of gp120 (SU) and gp41 (TM).

Antiretroviral therapy

The HIV/AIDS pandemic has been radically transformed by the development of effective combination antiretroviral therapy (cART). While HIV rapidly evolves to evade antiretroviral monotherapy, combination therapy is effective in suppressing viral load and dramatically prolonging survival, allowing infected individuals to live relatively healthy lives with an infection that until recently meant almost certain death. Current antiretroviral therapies target several aspects of the viral replication cycle. Nucleoside analogs (NRTIs) function as reverse transcriptase inhibitors by their capacity to be incorporated by RT during DNA synthesis. Since these nucleoside analogs lack the 3'-OH, DNA synthesis cannot proceed upon NRTI incorporation. Resistance to NRTIs occurs when mutations associated with increased efficiency of incorporation of the natural substrates relative to the nucleoside analog are accumulated. Other mutations can allow RT to gain the capacity to excise the unnatural nucleoside after incorporation. While the NRTIs inhibit reverse transcription by mimicking the natural substrates of RT, nonnucleoside reverse transcriptase inhibitors (NNRTIs) function as small, hydrophobic molecules that inhibit RT by an allosteric mechanism. NNRTIs are only effective against RT from subtypes B and C of HIV-1, as most retroviral RT enzymes, including those of HIV-1 group O, HIV-2, and SIV, lack the NNRTI binding pocket and are naturally resistant. Even in HIV-1 subtypes B and C, resistance mutations to NNRTIs develop easily. Integrase strand transfer inhibitors (INSTIs) target HIV integrase, preventing successful integration of the viral DNA genome and promoting the formation of nonproductive intermediates, such as 2-LTR circles. Protease inhibitors mimic the transition state for normal HIV protease substrates and block the enzyme active site. These inhibitors, however, carry particularly burdensome side effects, and thus are not utilized in first-line cART in most cases.

Latency

Despite the success of cART, it does not represent a cure, and infected individuals must remain on cART for the remainder of their lives. Although viral loads are suppressed below clinically detectable levels, viral rebound occurs within a few weeks of cessation of cART. Thus, despite the capacity of cART to virtually eliminate the pool of replicating virus in an individual, latent reservoirs of the virus exist in which an integrated provirus remains transcriptionally silent, evading detection by host immune responses or ART. These latent reservoirs are established early during the course of infection and represent a major barrier to curing HIV-infected individuals.

The current approaches to developing a cure for HIV involve reactivating these latent reservoirs in a so-called shock-and-kill approach. Once the previously latent proviruses are "shocked" to be reactivated, they can be "killed" by viral cytopathic effect or by the host immune system while cART prevents infection of new cells and reseeding of the latent reservoir. There are many such approaches to reactivate latent proviruses, including inhibitors of histone deacetylases, T cell activators, and activators of NF- κ B and P-TEFb, although to date none of these approaches have proved successful in significantly reducing the size of the latent reservoir and substantially delaying rebound upon cessation of cART.

HTLV Diseases

HTLV-1 can cause adult T cell leukemia/lymphoma (ATL) or HTLV-associated myelopathy/tropical spastic paraparesis (HAM/TSP) in a minority of infected individuals. Despite similarities with HTLV-2, -3, and -4, only HTLV-1 is known to cause disease. HTLV is a complex deltaretrovirus, encoding Tax to enhance gene expression by recruiting CREB to the viral promoter, as well as Rex to enhance export of unspliced and incompletely spliced RNAs. Tax can also be deleterious to the virus when over-expressed, as it is the dominant antigen recognized by effective CD8⁺ T cell responses. These responses successfully control the infection in most carriers, although deficiencies in CD8⁺ T cell lytic capacity are observed in HAM/TSP patients. Thus, the virus has evolved to suppress *tax* mRNA transcription with the HBZ accessory protein, while also suppressing nuclear export of *tax* transcripts with p30.

HTLV-1 infects T cells, B cells, and monocytes, and disease is mediated by Tax, which activates NF κ B to induce immortality and growth, inhibits p53, p16, and MAD1 to prevent apoptosis, and inhibits tumor suppressive TGF- β signaling, all of which promote oncogenesis. HBZ may also contribute to disease maintenance. This can lead to the onset of adult T cell leukemia/lymphoma, as well as inflammatory disease such as HAM/TSP. Leukemia enhances the spread of the virus, which replicates poorly within the host due to effective CD8⁺ T cell responses, by causing clonal expansion of infected cells. Rather than free virus particles, which are low in abundance in infected individuals, infected cells mediate transmission of the virus through sexual contact, blood transfusion, needle sharing, or breast milk. Other deltaretroviruses, such as bovine leukemia virus and simian T cell leukemia virus, can also cause lymphoid malignancies, similar to HTLV-1.

Endogenous Retroviruses (ERVs)

Due to their fascinating and unique capacity to integrate the viral DNA genome into the infected cell genome, retroviruses have a distinct potential for endogenization, the process of incorporating viral genetic material into the endogenous host genome through infection of germline cells. Once a retrovirus has been endogenized, it can be transmitted vertically through the population. Upon germline insertion, endogenous retroviruses (ERVs) can drive evolution through insertional mutagenesis, as well as immediately providing new genetic information in the form of the viral genome. Natural selection dictates that only ERVs with nondeleterious insertions persist in the population, and over time ERVs accumulate mutations to lose their pathogenic potential. Eventually some endogenous retroviral sequences can be hijacked for the benefit of the host, as in the example of the syncytin genes, which are derived from retroviral *env* genes and are essential for the formation of the mammalian placenta. The retroviral provirus shares many

similarities with the retroelements found in the genomes of virtually all living things. ERVs represent a common form of retroelement in vertebrates, where hundreds of thousands of copies of ERVs make up 1%–10% of vertebrate genomes. By comparing ERV sequences and integration sites across species, valuable insight into the evolutionary relationships among vertebrate species can be inferred. As retroviral integration site selection is virtually random, identical integration sites of ERVs between species or individuals imply that the exogenous retrovirus was endogenized in a common ancestor.

ERVs that still contain the *pol* gene can be classified based on the sequence of reverse transcriptase and divided into three classes: Class I ERVs are related to gammaretroviruses and epsilonretroviruses, Class II ERVs are related to alpharetroviruses, betaretroviruses, and lentiviruses, and Class III ERVs are related to spumaviruses. Most ERVs are grossly defective, containing numerous stop codons or frameshift mutations, and they are frequently transcriptionally silenced by various host mechanisms, including heavy methylation of the surrounding DNA. The vast majority of ERVs, known as solo-LTRs, have experienced a drastic recombination event between the two LTRs, removing all of the viral sequence and preserving only a single LTR.

Defective ERVs can still be transcribed to produce RNAs under conditions of cellular stress or differentiation, and these RNAs can be packaged in the context of an exogenous retroviral infection, so long as they maintain the necessary cis-acting packaging signals. ERVs that maintain some functionality can replicate if the essential missing functions are provided in trans by other ERVs, LTR retrotransposons, or exogenous retroviruses. The frequency with which this occurs is dependent on the ERV. Human ERVs are predominantly silent, with no actively-replicating members described. Koala retrovirus, however, is currently in the process of endogenization, with both exogenous and endogenous virus transmitted through the population, and with endogenous viruses likely spreading by both vertical and horizontal transmission.

Gene Therapy Vectors

The capacity of the viral genome to stably integrate into the host cell genome has made retroviruses a particularly attractive candidate for gene therapy delivery vectors. Successful integration can lead to sustained, persistent expression of the transgene throughout the life of the cell and all its progeny. Retroviruses are also particularly amenable to pseudotyping with different envelope proteins, which allows for selection from a wide range of tropisms to deliver the vector to particular target cells within the patient. Early clinical trials using MLV vectors to treat X-linked severe combined immunodeficiency (X-SCID) were successful, but one fourth of the patients developed clonal T cell leukemias resulting from integration-induced activation of a cellular proto-oncogene. The recent determination that MLV preferentially integrates near transcription start sites (TSS), increasing the likelihood of such outcomes, has led to the design of retroviral vectors that minimize undesirable outcomes.

Lentiviruses tend to integrate in the middle of actively transcribed genes, limiting the risk that they will activate transcription of a silent gene or integrate near a TSS. In addition, lentiviruses can infect nondividing cells, which makes them a preferred vector for targeting nonproliferative cell types. Thus, lentiviral vectors are the predominant retroviral gene therapy vectors in development today. These efforts focus on the use of replication-incompetent viruses, lacking some combination of *gag*, *pol*, and *env*, which are provided in *trans* in the producer cells to generate gene delivery vectors capable of only a single-round infection. However, the risk remains that recombination could occur in the producer cell, especially with cross-packaging of endogenous retroviral genomes, which could result in the production of a replication-competent virus. While such events are exceedingly rare, the risk of infecting an individual with a replication-competent lentivirus is an important consideration in developing safe retrovirus-based gene therapy approaches.

© 2019 Elsevier Inc. All rights reserved.

Glossary

Extracellular DNA Extracellular DNA (also called naked, free, ambient, or environmental DNA) are DNA fragments released into the environment from decomposing cells, disrupted cells, or viral particles, or via excretion from living cells.

Heterogamic/interspecific transformation Heterogamic/interspecific transformation leads to recombination between chromosomal DNA from different species.

Homogamic/intraspecific transformation Homogamic/intraspecific transformation leads to recombination between chromosomal DNA within species.

Recipient Recipient is a bacterial cell that has the potential to acquire DNA by natural transformation.

Synten Synten describes the observation of shared presence and order of genes on the chromosomes of related species. Disruption of synten due to genetic rearrangements may reduce recombination rates within and between the species.

Transformant Transformant is a bacterial cell that has successfully acquired DNA by natural transformation.

Transformation frequency Transformation frequency is usually given as the number of transformant bacteria divided to the total number of recipient bacteria of a given species over a given time period.

Abbreviations

CDS	Coding sequence
GMM	Genetically modified microorganism
GMO	Genetically modified organism
HFIR	Homology-facilitated illegitimate recombination
HGT	Horizontal gene transfer
MEPS	Minimum efficient processing segment
MR	Mismatch repair
RM	Restriction modification
SSBP	Single-strand binding proteins
USS	Uptake signal sequences

Defining Statement

Here we present experimental models that examine the uptake of chromosomal DNA in bacteria and discuss some of the advantages and limitations of the models used. The relationship between DNA uptake frequencies versus selection is examined, and the implications for the open release of genetically engineered microbes are discussed.

Process of Natural Uptake of Extracellular DNA in Bacteria

Extracellular DNA released from a donor organism can be “horizontally” acquired by bacteria (recipients) through the process of natural transformation. Natural transformation occurring with chromosomal DNA fragments can be divided into several steps (Thomas and Nielsen, 2005):

[☆]*Change History:* February 2016. S Domingues and KM Nielsen added an abstract and keywords and revised and updated text throughout chapter. References to more than 170 scientific studies were added. A new Table (1) is included and the previous Table 1 is now Table 2. The sub-sections “HGT in bacteria belonging to the microbiome” and section “Clinical relevance of HGT and antibiotic resistance” were added and the section on gene transfer in food was expanded with input from M. Woegerbauer. The many revisions lead to changes in authorship and we thank P. J. Johnsen and J. L. Ray for contributions to the earlier version of this chapter.

This article is an update of K.M. Nielsen, J.L. Ray, P.J. Johnsen, Horizontal Gene Transfer: Uptake of Extracellular DNA by Bacteria, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 587–596.

1. Development of competence (physiological state for DNA uptake) in the recipient bacterium simultaneously with exposure to transforming DNA;
2. DNA uptake/active translocation into the bacterial cytoplasm;
3. Heteroduplex formation of transforming DNA with similar DNA sequences in the recipient chromosome;
4. Homologous recombination-mediated integration of the transforming DNA strand into the recipient bacterium's chromosome;
5. Expression of the acquired trait(s) leading to an altered recipient phenotype; and
6. Stable inheritance and maintenance of the acquired trait(s) at the individual recipient cell level and at the bacterial population scale level.

Although the last two steps are not strictly part of the transformation process, they are usually an integral part of most natural transformation studies in bacteria. Extracellular DNA is only accessible to naturally transformable bacteria when they are in a competent state. Competence is a genetically encoded physiological state in which bacteria express protein complexes that facilitate uptake of DNA into their cytoplasm (Dubnau, 1999; Chen and Dubnau, 2004; Claverys and Martin, 2003). In bacteria such as *Streptococcus pneumoniae* and *Bacillus subtilis*, competence is under tight regulation by a cell-to-cell signalling pathway; for other bacteria, such as *Neisseria gonorrhoeae* and *Helicobacter pylori*, DNA can be taken up during all phases of growth (Seitz and Blokesch, 2013). Competence development is usually linked to particular growth conditions or perturbation of those conditions. For instance, *Acinetobacter baylyi*, a soil and water bacterium, achieves maximum competence for DNA uptake during growth at early and late exponential phase (Palmen et al., 1993; Ray and Nielsen, 2005). In *B. subtilis*, random peak levels of the ComK global regulator protein trigger transition to a competent stage (Maamar et al., 2007). Bacteria that can express natural genetic competence are found in diverse habitats, and it is suspected that discovery of more naturally competent species and strains will continue with further improvement of culture- and nonculture-based methods of detection of DNA uptake (Claverys and Martin, 2003; Johnsborg et al., 2007). The reasons for the existence of DNA uptake/integration mechanisms in bacteria are still debated; incoming DNA fragments may be used for nutrition after further degradation, as a template for recombinational repair of DNA, for movement or for the recombination of existing variation in the population and generation of new genetic variation of which some may accelerate adaptation (Redfield, 1993; Chen and Dubnau, 2004; Bakkali, 2013). Natural transformation may serve different functions in different bacterial species, as evidenced by expression of competence at dissimilar stages in their life cycles and to varying extents (Baltrus and Guillemin, 2006; Dorer et al., 2010; Johnston et al., 2014).

The model organisms *A. baylyi*, *B. subtilis*, *Haemophilus influenzae*, *H. pylori*, *N. gonorrhoeae*, *S. pneumoniae*, and *Vibrio cholerae* have provided most of the information about the molecular aspects of the natural transformation process (Johnston et al., 2014). The DNA translocation apparatus is a putative pore-forming multimeric protein complex that spans the inner membrane/periplasm/outer membrane in Gram-negative bacteria, and the inner membrane/cell wall in Gram-positive bacteria (Averhoff and Graf, 2008; Chen and Dubnau, 2004; Kruger and Stingl, 2011). The DNA uptake machineries of Gram positive and Gram negative bacteria are remarkably similar. Both DNA uptake and processing relies on a comparable arsenal of competence (*com*) genes. The expression of *com* regulons is nevertheless controlled by a variety of competence regulators suggesting different triggers of competence development (Johnston et al., 2014). Extracellular DNA first binds to the translocation apparatus on the cell surface by a poorly understood mechanism. While *N. gonorrhoea* (Graves et al., 1982) and *H. influenzae* (Sisco and Smith, 1979) require specific uptake signal sequences (USS) for successful DNA binding and translocation, the majority of bacteria will bind extracellular DNA non-discriminatory with respect to sequence. Natural transformation can occur by both linear and circular donor DNA (Thomas and Nielsen, 2005). Structural proteins associated with extracellular DNA do not hinder the DNA-binding or uptake process, as bacterial cell lysates also efficiently transform competent bacteria (Nielsen et al., 2000a). Although the DNA is initially double-stranded, it enters the bacterial cytoplasm in single-stranded (ssDNA) form, providing evidence for an endonuclease within, or associated with, the membrane-bound translocation apparatus that degrades one strand during DNA uptake (Chen and Dubnau, 2004; Johnston et al., 2014). The uptake of DNA by competent cells is directional (Barany et al., 1983), and occurs at rates of up to 100 bp s⁻¹ (Mejean and Claverys, 1993). Studies on the size of chromosomal DNA substrates in bacteria have demonstrated that the initial DNA fragment size is not correlated to uptake efficiency but to integration efficiency. Longer DNA fragments are more likely to yield detectable transformants in *in vitro* assays than shorter fragments (Palmen and Hellingwerf, 1997; Pifer and Smith, 1985). In some cases, part of the translocated DNA can be degraded in the cytoplasm prior to chromosomal integration; for example, approximately 500 and 1500 bp at each end of the linearized strand are degraded in *A. baylyi* (Palmen and Hellingwerf, 1997) and *H. influenzae* (Pifer and Smith, 1985), respectively.

Few details are available on the molecular interactions of ssDNA once it enters the cytoplasm of studied bacterial species. There is evidence that single-strand binding proteins (SSBP) or other proteins (eg, RecA) bind to the DNA fragment and provide protection from rapid nucleolytic degradation (Claverys et al., 2009). Although the majority of DNA molecules that enter the bacterial cytoplasm will be degraded, some of the DprA and RecA-associated ssDNA may subsequently pair with the bacterial chromosome by homology-guided base-pairing at the cognate locus in the recipient (Berge et al., 2003; Johnston et al., 2014). For heterogamic transformation (ie, recombination between chromosomal DNA from different species), the formation and stability of the heteroduplex molecule formed by donor strand base-pairing is determined by the degree of sequence similarity between the donor and recipient DNA. If the incoming chromosomal DNA is less than approx. 30% divergent from the recipient genome, integration by homologous recombination may occur into the host genome (de Vries and Wackernagel, 1998; de Vries et al., 2001; Majewski and Cohan, 1998; Majewski et al., 2000; Matic et al., 1997; Vulic et al., 1997). Lack of DNA similarity and, hence, stable heteroduplex formation is, for example, the most likely hindrance to interspecific recombination in *Bacillus* spp. (Roberts and Cohan, 1993), *Streptococcus* spp. (Majewski et al., 2000), and *Acinetobacter* spp. (Ray et al., 2009).

The most common type of recombination in bacteria is thought to occur when sequence similarity between the donor and recipient DNA is uniformly present over the entire heteroduplex region. In cases where the donor and recipient sequences are identical along their entire lengths, recombination with the donor DNA strand will not produce a detectable genetic or phenotypic change. In cases where some minor sequence dissimilarity between donor and recipient exists, successful transformation events yield the acquisition of donor polymorphisms in transformants (ie, allelic replacement). This process is called substitutive recombination, as the resulting DNA sequence in a transformant originates by substitution of the recipient sequence with (parts of) the donor sequence. Such substitutive recombination leads to mosaic gene formation when the recombining regions are of limited size. Such recombination events do not introduce major insertions or deletions and typically do not disrupt the overall coding sequence (CDS) and reading frame if a protein-encoding gene is present in the recombined region.

A second type of recombination process occurring in natural transformation is called additive integration. Such a recombination process occurs when a defined DNA sequence present only in the donor is flanked on both sides by sequences common to both donor and recipient bacteria. Heteroduplex formation occurring at flanking regions with high DNA similarity results in recombination of those sequences, as well as integration of the intervening foreign sequence, into the recipient chromosome. Similarly, recombination at homologous flanking segments can lead to loss of DNA (eg, IS elements or prophages) in the recipient.

Additive or substitutive integration may also occur in the presence of only one-sided homology/DNA similarity between donor and recipient. Such homology-facilitated illegitimate recombination (HFIR) allows additive integration of an incongruous DNA sequence via a recombinational anchor of homologous/similar sequence at one end of the invading DNA strand and a random microhomology (3–10 nucleotides) at the other end. HFIR events often result in nonspecific deletion of a recipient DNA sequence located between the anchor and the downstream microhomology. HFIR has been demonstrated as a mechanism of foreign DNA integration by natural transformation in *A. baylyi* (de Vries and Wackernagel, 2002), *S. pneumoniae* (Prudhomme et al., 2002), and *Pseudomonas stutzeri* (Meier and Wackernagel, 2003). The activity of the DNA maintenance machinery, combined with mutations and selection of the host chromosome, may over time produce a nucleotide composition including codon usage of the integrated fragment resembling that of the recipient. Also, a gradual elimination of DNA stretches may occur as a result of the combined outcome of recombination and population scale processes (mutations-deletions, genetic drift and negative selection).

A fourth type of recombination, illegitimate recombination, can occur also in the absence of DNA sequence similarity (eg, <70% DNA similarity) between the donor and the recipient bacteria (Hulter and Wackernagel, 2008). However, in contrast to many eukaryotic systems, illegitimate recombination of nonmobile chromosomal DNA in competent bacteria is rarely reported. Random insertion of foreign DNA in bacterial genomes most often results in a reduction in the relative fitness of the transformant (Elena et al., 1998). It can, therefore, be hypothesized that such events are extremely rare in bacterial populations and the forces modulating recombination frequencies in bacteria are complex (Fig. 1).

Natural transformation by DNA fragments encoding their own mobility and stabilization functions (eg, mobile DNA such as plasmids) may occur independent of RecA and recombination with the bacterial chromosome as these can recircularize and replicate in the bacterial cytoplasm. The stable uptake of plasmid DNA in competent bacteria usually occurs at lower frequencies than the integration of chromosomal DNA fragments due to reassembly constraints on the plasmid fragments in the cytoplasm (Skippington and Ragan, 2011; Thomas and Nielsen, 2005). Recently, it was also shown that very short DNA fragments (<100 bp) could recombine with the bacterial genome in a recA independent manner (Overballe-Petersen et al., 2013). Additionally, transposition of mobile elements like transposons and composite-transposons can also occur in the bacterial cytoplasm after uptake of DNA fragments containing these mobile genetic elements (Domingues et al., 2012c). Thus, recent studies suggest several types of DNA fragments can become heritably stable after uptake in the bacterial cytoplasm even in the absence of DNA sequence similarity, RecA or an origin of replication.

The resulting recombined locus in the transformant bacterium may contain genetic alterations in existing noncoding (eg, regulatory) or protein-coding sequence, or larger alterations such as changed gene composition, gene order (synteny), and so on. It is noted that single DNA exposure event/transformation period may lead to multiple recombination events in a single bacterial genome (Mell et al., 2011). This can occur when the DNA source is for instance genomic DNA from the same bacterial species as the competent recipient bacterium. The various combinations of these factors may result in favourable, unfavourable, or

Fig. 1 Recombination frequencies may vary according to the metabolic (fitness) costs and benefits for the transformant. Recombination events can increase transformant fitness via rare acquisition of novel beneficial traits. Recombination rates are kept low by the high deleterious recombinational load associated with accumulation of deleterious sequences and the costs associated with production and maintenance of DNA translocation/recombination machinery. Recombination rates may be raised by the metabolic costs associated with frequent removal of unsuccessful recombination intermediates by DNA mismatch repair.

near-neutral fitness changes to the transformed bacterium that will ultimately determine the impact and the survival of the transformant in a dynamic bacterial population over time (Andersson, 2003).

Uptake of Extracellular DNA by Bacteria Present in Various Environments

Extracellular DNA molecules are released into the environment from decomposing cells, disrupted cells, or viral particles, or via excretion from living cells (Thomas and Nielsen, 2005). Release of intact DNA from decomposing cells depends on the activity and location of intracellular nucleases and reactive chemicals. DNA released from dead cells will be usually associated with the constituents of the cell cytoplasm, membrane, and DNA-binding proteins. Additionally, there are some bacterial species that trigger active release of DNA by killing noncompetent cells, a phenomenon called fratricide (Claverys et al., 2007; Johnsborg et al., 2008).

The first indication of the capacity of bacteria to take up extracellular DNA was published in 1928 by Griffith, when avirulent nonencapsulated *Streptococcus pneumoniae* in mice were “transformed” into the virulent, capsulated form after exposure to a capsulation “factor” from heat-killed virulent cells (Griffith, 1928). The experiments of Avery, MacLeod, and McCarty in 1944 identified as the transforming factor in Griffith’s experiments (Avery et al., 1944). Natural transformation studies of *B. subtilis* (Anagnostopoulos and Spizizen, 1961; Spizizen, 1958) and *H. influenzae* (Alexander and Leidy, 1951; Goodgal and Herriott, 1961) followed. Researchers then expanded studies to investigate interspecific genetic exchange in *Streptococcus* spp. (Majewski et al., 2000; Perry and Kuramitsu, 1981), between *Haemophilus* spp. (Albritton et al., 1984), and between different species of *Bacillus* (Harford and Mergeay, 1973; Majewski and Cohan, 1999). The ability to take up extracellular DNA by natural transformation has since been detected in a range of divergent subdivisions of bacteria, including representatives of the Gram-positive, cyanobacteria, *Thermus*, *Deinococcus*, green-sulfur bacteria, and numerous Gram-negatives (Johnsborg et al., 2007; Lorenz and Wackernagel, 1994; Paget and Simonet, 1994). Examples of naturally competent bacterial species are presented in Table 1. There is also evidence that some archaea could undergo transformation (Johnsborg et al., 2007), as well as the single-celled eukaryote *Saccharomyces cerevisiae* (Nevoigt et al., 2000). The phylogenetically widespread ability to acquire genetic information by natural transformation suggests that it may be functionally important in the environment. The limited number of transformable species identified may be explained by an overall lack of competence in the test populations, inability to obtain sufficient testable population sizes and time scales in the laboratory, or inability to recreate competence-inducing conditions as they occur under natural conditions (Johnsborg et al., 2007).

Uptake of DNA by Soil Bacteria

A number of divergent bacterial species present in soil, including *A. baylyi*, *B. subtilis*, *P. stutzeri*, and *Thermoactinomyces vulgaris* are known to be naturally transformable (Hopwood and Wright, 1972; Paget and Simonet, 1994). So far, all the published studies with soil-derived bacteria have been conducted in laboratory microcosms with sterile or nonsterile soil samples. Often, the soils have been amended with clay minerals or nutrients prior to or during the transformation experiments. Natural transformation of bacteria in the field remains to be shown, possibly due to the experimental challenges in both identifying and quantifying low-frequency events occurring in bacterial communities reaching 10^9 bacterial cells per gram of soil (Mercier et al., 2006; Paget and Simonet, 1994). Some of the first transformation studies on soil reported that the commonly occurring Gram-positive bacterium *B. subtilis* takes up chromosomal DNA when grown in autoclaved potting soil (Graham and Istock, 1978, 1979). Many subsequent studies have investigated natural transformation of *B. subtilis* cells in soil with chromosomal and plasmid DNA (Gallori et al., 1994, 1998). Often, the addition of clay minerals (1–10%, w/w) such as montmorillonite has been shown to increase DNA stability and transformation frequencies (Lee and Stotzky, 1990, 1999). Natural transformation of the Gram-negative *P. stutzeri* cells has been shown in sterile soil slurry with chromosomal DNA (Paget and Simonet, 1997), and in a nonsterile soil microcosm with plasmids, chromosomal DNA, and intact bacterial cells (Sikorski et al., 1998). While most studies in soil microcosms have relied on the addition of purified DNA, natural transformation of the Gram-negative *A. baylyi* has also been shown after the addition of isogenic cell lysates or lysates from *Pseudomonas fluorescens* or *Burkholderia cepacia* (Nielsen et al., 2000a). The detection of DNA uptake was based on recombinational repair of a partially deleted neomycin phosphotransferase gene (*nptII*) in the recipient with a functional *nptII* gene transferred from the donor bacteria. While most studies of natural transformation in soil have relied on the addition of competent cells to the microcosms, some studies have also shown that competence for natural transformation can develop *in situ* (Nielsen and van Elsas, 2001; Nielsen et al., 1997; Nielsen et al., 2000a, b).

Several investigations have explored the possibility that plant transgenes, such as antibiotic resistance markers, can be released from decaying genetically modified plants and be exposed to competent soil- and plant-associated bacteria. Short fragments of plant DNA have been shown to remain stable for up to several years in agricultural soil (Nielsen et al., 2007). Soil microcosms have been used to investigate the possible transfer of the kanamycin and hygromycin resistance genes (*nptII*, *hpt*) from tissue homogenates of transgenic tobacco (*Nicotiana tabacum*) plants into indigenous soil bacteria (Becker et al., 1994). However, no bacterial transformants could be recovered. This investigation hypothesized that any integration of the plant marker genes into the genome of exposed soil bacteria would take place after illegitimate recombination. The only studies that show uptake of DNA fragments isolated from transgenic plants into a soil-residing bacterium utilize a recipient strain with inserted sequence similarity to the plant marker gene *nptII* (de Vries and Wackernagel, 1998; Nielsen et al., 2000b). For example, using this system, Nielsen and colleagues (Nielsen et al., 2000b) have shown that the uptake of the plant marker gene in the bacterium *A. baylyi* in a sterile soil microcosm occurred at frequencies of 1×10^{-7} transformants per plant-harboured copy of the *nptII* gene. The amount of DNA added was

several orders of magnitude higher than the concentrations expected to be released from plants under their natural growth cycle. There is no evidence to date for stable incorporation and inheritance of plant DNA in bacteria in the absence of supplied DNA sequence similarity.

Soil is a spatially and structurally heterogeneous environment in which numerous microhabitats exist. The current empirical knowledge of natural transformation in soil has been exclusively collected in soil microcosms. Most often, the studies have relied on external addition of high concentrations of DNA, bacterial cells, nutrients, or clay minerals to either sterile soil (all studies prior to 1997) or nonsterile soil samples. Moreover, the transformation frequencies recorded in soil represent so far a broad distribution across a heterogeneous milieu. The detection of rare natural transformation events under more realistic conditions depends on advances in methodology to allow more sensitive identification and quantification in the locations in soil that are conducive to natural transformation.

Uptake of DNA by Plant-Associated Bacteria

Both transduction and conjugation have been shown to occur on plant surfaces (Kidambi et al., 1994; Lilley and Bailey, 1997). However, few studies have examined horizontal gene transfer (HGT) by natural transformation on plant surfaces or plant tissues. A growing interest in gene transfer mechanisms active in these environments has been stimulated by the presence of engineered genes (transgenes) in genetically modified plants. Candidates for exposure to plant transgenes are bacteria that interact closely with plant cells, for example, epiphytes, endophytes, rhizosphere bacteria, and plant pathogens. Several studies have examined the potential of DNA uptake in plant-associated bacteria (Nielsen et al., 2001). Uptake of plant marker genes has been examined in the plant pathogen *Agrobacterium tumefaciens* in, for example, tobacco crown-galls (Broer et al., 1996), in transgenic potato tubers infected with a pathogenic *Erwinia chrysanthemi* strain (Schluter et al., 1995), and *Ralstonia solanacearum*-infected tomato plants (Bertolla et al., 1999, 2000). Kay et al. (2002) reported successful transformation of *A. baylyi* cells with plastid DNA transplastomic tobacco plants. Transformation occurred *in situ* under greenhouse conditions in plants cocolonized with the bacterial pathogen *Ralstonia solanacearum*. Host plant DNA uptake was later also directly visualized with genes encoding green fluorescent protein

(Rizzi et al., 2008; Pontiroli et al., 2009). The general 1000-fold larger size of a plant genome, as compared with a bacterial genome, effectively dilutes the concentration of particular genes in plant DNA such as the selectable gene examined for transfer (Arumuganathan and Earle, 1991; Bertolla et al., 2000). Transgenes inserted into plant organelles may have higher copy numbers and higher sequence similarity to bacterial chromosomes than transgenes inserted into the plant chromosomes. Recent studies have shown that bacteria can access plant DNA during colonization of plants, or after mechanical disruption of plant tissues, if regions of high DNA similarity exist between the plant and bacterial DNA (Rizzi et al., 2008; Pontiroli et al., 2009). Thus, the main mechanistic barrier to the uptake and integration of plant transgenes in bacteria seems to be the limited DNA exposure and opportunity for homologous recombination to occur due to the limited extent of sequence similarity between plant transgenes and bacterial genomes. If such gene transfer occurred under natural conditions, constraints to efficient sampling makes it unlikely it would be detected in the short term (Nielsen and Townsend, 2004; Pettersen et al., 2005; Townsend et al., 2012).

Uptake of DNA by Bacteria in Water and Sediment

Marine environments can contain significant concentrations of dissolved DNA (Deflaun et al., 1987). Several studies have examined the ability of both introduced and native bacteria to take up DNA by natural transformation in water and sediment microcosms (Day, 2000). The studies can be divided into those that introduce defined bacterial inoculants (recipients) or purified selectable DNA (eg, containing an antibiotic resistance marker gene) into marine microcosm environments to detect DNA uptake events, and those that expose selected members of the indigenous population to DNA containing selectable markers *in vitro*. In studies utilizing introduced bacterial recipients, natural transformation has been shown in the *Vibrio* spp. strain WJT-1C (Paul et al., 1991) (later reclassified as a pseudomonad (Frischer et al., 1996)) with plasmid DNA in small-scale marine water and sediment microcosms sampled from the Eastern Gulf of Mexico; in marine sediments inoculated with the *P. stutzeri* and added chromosomal DNA (Stewart and Sinigalliano, 1990; Stewart et al., 1991); in *A. baylyi* with chromosomal DNA in groundwater samples from a drinking water well, sterile aquifer material, and in sterile groundwater microcosms (Chamier et al., 1993; Lorenz et al., 1992); and in *B. subtilis* with chromosomal and plasmid DNA bound to mineral aquifer material (Romanowski et al., 1993).

In the first experiments to describe natural transformation in open systems, an introduced *A. baylyi* strain was capable of being transformed to prototrophy by bacterial cell lysates or live donor cells in different river systems (Williams et al., 1996). The recipient *A. baylyi* bacteria and transforming DNA were immobilized on filters secured to stones on the riverbed. Transformation frequencies of 10^{-6} to 10^{-3} were reported.

In native bacterial populations, natural transformation of marine bacteria has been recorded after exposure to plasmid DNA or DNA in cell lysates of rifampicin-resistant *Vibrio* strains (Frischer et al., 1994). Three out of 30 marine bacterial isolates were found to be competent for uptake of the plasmid DNA in *in vitro* assays. These included isolates of the genera *Vibrio* and *Pseudomonas*. Moreover, 15 out of 105 sensitive isolates obtained from Tampa Bay (FL, USA) were found to acquire rifampicin resistance in *in vitro* assays. In another set of experiments, plasmid DNA exposure of 14 different whole bacterial communities sampled from a variety of marine environments, such as sediment, surface, and deep water, and from various organisms revealed that bacteria present in 5 out of the 14 communities examined could take up DNA (Frischer et al., 1994). This study estimated that between 0.000 05 to 1 transformant occurred per litre of water per day, suggesting that natural transformation may be an important mechanism for plasmid transfer among marine bacterial communities. In general, experimental studies suggest that DNA present in freshwater, in marine water, and on sediment surfaces is available for natural transformation of competent bacteria of the genera *Acinetobacter*, *Bacillus*, *Pseudomonas*, and *Vibrio*, albeit at variable frequencies that depend on environmental conditions and the type of DNA present. The introduction of defined recipient bacteria into an environmental sample results in competition between the introduced recipient population and indigenous communities for nutrients, habitats, and transforming DNA. This presents a challenge in the design of experiments that accurately reflect the environmental conditions, species compositions, and concentrations encountered by recipient bacterial strains when present in natural habitats.

Uptake of DNA by Bacteria Present in the Digestive System

The potential for competence has been identified in few bacteria isolated from the digestive system. Most studies have focused on members of the Gram-positive genus *Streptococcus* that are ubiquitous in the human oral cavity, as well as in rumen of many higher animals including cattle and sheep (Frandsen et al., 1991; Jarvis et al., 2001; Jayne-Williams, 1979; Savage, 1977). Several microcosms and *in vitro* systems have been applied to detect DNA uptake in *Streptococcus* spp. Sampling the teeth of 70 human individuals, it was found that at least 20 out of 129 isolates identified as *Streptococcus mutans*, which forms biofilms in dental plaques, could develop competence for acquisition of chromosomally borne streptomycin resistance *in vitro* (Westergren and Emilson, 1983). In a more recent study (Li et al., 2001), high natural transformation frequencies were reported, reaching up to three transformants per 100 exposed recipients, using *S. mutans* cells grown in biofilms on polystyrene microtiter plates and saturating concentrations of DNA. The transformation frequencies of the surface-bound cells were 10- to 600-fold higher than those observed for planktonic *S. mutans* cells. Natural transformation was also observed when *S. mutans* cells were exposed to biofilms of a heat-killed isogenic strain harbouring an erythromycin resistance gene (Li et al., 2001). Natural transformation of *Streptococcus gordonii*, also found in the human oral cavity, has been reported by plasmid or chromosomal DNA in saliva samples at frequencies up to 7×10^{-4} transformants per recipient cell (Mercer et al., 1999b). Naturally transformable bacteria can therefore, potentially take up DNA from food sources within the mouth. The natural transformation of a ruminal bacterium was first reported in 1999 with

Streptococcus bovis cells at a frequency of 1×10^{-5} transformants per microgram plasmid in a liquid culture medium (Mercer et al., 1999a).

Currently, only a few bacterial species localized to the digestive system of higher animals have been found to express competence *in vitro* and none have been found *in situ* (Nordgard et al., 2012). Few studies have examined or reported on the potential development of competence by bacteria colonizing invertebrates (Deni et al., 2005; Ray et al., 2007). The scarcity of available data may be due to insufficient incentive and methods to investigate limited bacterial transformability in such habitats. Although several members of the genus *Streptococcus* have been found to develop competence *in situ*, and other bacteria inhabiting the animal digestive tracts like *H. pylori* and *Campylobacter* spp. can develop competence *in vitro*, the biological significance of horizontal acquisition of extracellular DNA in the digestive system remains unclear.

Uptake of DNA by Bacteria Present in Food

Food provides an excellent growth substrate for many types of microorganisms. Some evidence exists for the uptake of extracellular DNA by bacteria residing in food. Natural transformation of *B. subtilis*, a common contaminant in milk, ranges from 10^{-4} to 10^{-3} transformants per recipient, with the highest frequency of 3×10^{-3} obtained in chocolate milk after an incubation time of 12 h at 37°C (Brautigam et al., 1997). Additional studies have also demonstrated the successful transformation of *B. subtilis* in milk products (Wittke et al., 2002; Zenz et al., 1998). Plasmid transfer by natural transformation of *Escherichia coli* in various foods, including milk, soy drink, tomato juice, carrot juice, vegetable juice, supernatants of canned cabbage, soy beans, shrimps, and various mixtures of canned vegetables, has also been shown to occur (Bauer et al., 1999). Natural transformation occurred in all growth substrates, although at variable frequencies. Typically, fewer than 10^{-8} transformants per recipient cell were observed, at frequencies three or four orders of magnitude lower than those of transformation experiments conducted under optimized laboratory conditions. No correlation was found between the content of divalent ions such as Ca^{2+} , which are considered prerequisites for artificial transformation of *E. coli*, in the foods and transformation frequencies. Natural transformation of *E. coli* on solid surfaces simulating biofilm conditions could be established on vegetables (eg, cucumber, potato, onion, tomato, carrot, leek), fruits (orange, pear, pineapple, apple, melon, grape, persimmon), raw meat and fish (beef, chicken, pork, tuna, salmon) and processed foods (tofu, orange gelatin, strawberry jam, pudding, curry, butter) obtaining transformation frequencies between 10^{-6} and 10^{-8} (Maeda et al., 2004). The above studies exemplify that food sources may provide the conditions required for natural transformation to occur and that the bacterial contaminants of food can experience competence-inducing growth conditions.

Development of competence and the uptake of plasmid-borne DNA in spring and mineral water were demonstrated for laboratory strains of *E. coli* (Baur et al., 1996). Calcium concentrations as low as 1–2 mM were sufficient to obtain transformants. These amounts of calcium ions were readily available in natural aqueous habitats of calcareous regions (spring water: 3.1–3.3 mM; mineral water: 1.9–11.3 mM; tap water: 1.5 mM; river water: 0.3–2.4 mM) and in mammalian body fluids (saliva: 2.3 mM; ileum: 4.2 mM; urine: 5.9 mM) (Baur et al., 1996). Variation of the incubation temperature (ie, temperature shifts as usually required for artificial transformations of *E. coli*) was no prerequisite for induction of natural competence. Upon prolonged incubation of laboratory strains of *E. coli* in spring and bottled mineral water (ie, under naturally occurring conditions) transformation frequencies as high as 10^{-2} to 10^{-5} were observed.

Laboratory strains of *E. coli* laboratory used for cloning purposes are mutants usually with inactivated DNA endonucleases and not representative for the DNA maintenance machinery active in naturally occurring bacterial populations of this species. Transformation frequencies using wild type strains of *E. coli* from clinical specimens under similar conditions as described above were strikingly strain-dependent (Woegerbauer et al., 2002). Some strains were highly transformable showing transformation frequencies up to 10% of the laboratory strain comparator; some were not transformable at all or expressed fluctuating transformation phenotypes. This strain-dependent variation in transformability was also observed in other bacterial taxa (Bosse et al., 2009; Maughan and Redfield, 2009). Water with Ca^{2+} concentrations between 1 and 2.9 mM served as matrix for the generation of wild type transformants if a temperature shift (25–37°C) was applied. No transformants could be detected at constant incubation temperatures. Transformability of wild type strains was, thus, more stringently controlled by the kind of temperature shifts compared to laboratory strains (Woegerbauer et al., 2002). Induction of competence was rapid process: a 1-min incubation in water supplemented with CaCl_2 was sufficient for the formation of transformants. As transformation limiting factors, DNase-dependent DNA degradation, a low poly- β -hydroxybutyrate (PHB)-calcium-polyphosphate complex production and a low C/N ratio (ie, nutrient starvation) could be identified (Lorenz and Wackernagel, 1994; Baur et al., 1996).

These observations provided indications for an internal — physiological — regulation of competence in *E. coli* rather than a dependence on a physiochemical induction via non-physiological concentrations of divalent cat-ions and heat shock as applied during cloning experiments (Baur et al., 1996). The experimentally obtained data were subsequently complemented by the detection of competence genes (Cameron and Redfield, 2006) and competence regulator homologs in the *E. coli* genome (Sinha et al., 2009). *E. coli* thus contains a functional DNA uptake machinery (Sinha and Redfield, 2012). *E. coli* was shown to develop competence even on Ca^{2+} -deficient solid media and agar was identified as trigger (Maeda et al., 2004; Sun et al., 2006, 2009, 2013). The reluctance to accept inducible competence-specific natural transformability of *E. coli* may have been caused by the difficulty to identify the exact cue for the induction of the competence regulator protein (Sinha and Redfield, 2012).

HGT in Bacteria Belonging to the Microbiome

Both the oral cavity (Roberts and Kreth, 2014) and the gut (Modi et al., 2014) are rich in naturally competent bacteria, and these environments offer the opportunity for natural transformation within the local microbiome or between the microbiome and transient bacteria (Huddleston, 2014). In fact, the human intestinal tract is the largest natural reservoir for antibiotic resistance genes (Huddleston, 2014). It has been shown that bacteria present in fecal samples are mainly resistant to antibiotics that have been in use for longer periods and that are used in livestock (Forslund et al., 2013). Antibiotic treatment selects for resistant bacteria and offers opportunity for HGT (Allen et al., 2014; Modi et al., 2014), which ultimately leads to treatment failure.

Bioinformatics based studies suggest HGT events are 25 times more likely to occur in human-associated bacteria than bacteria from other environments (Smillie et al., 2011). For instance, the animal digestive system is hypothesized to be an environmental hot spot for bacterial gene transfer due to the high concentrations of nutrients, actively growing bacteria, and surface (Huddleston, 2014; Modi et al., 2014; Roberts and Kreth, 2014; Salyers, 1993). The microbiota of people with cystic fibrosis also comprise several species, including the naturally competent *H. influenzae*, offering the opportunity for horizontal transfer (Sherrard et al., 2014); *in vitro* experiments have shown the conjugal transfer of antibiotic resistance determinants present in *H. influenzae* isolates collected from cystic fibrosis patients (Roberts et al., 2011). Conjugation involving the local microbiota has also been shown in the gastrointestinal tract of humans (Huddleston, 2014). The human microbiota comprises numerous naturally transformable bacterial species (Modi et al., 2014). However, probably due to methodological constraints and other undetermined factors, little information is available on DNA uptake processes by natural transformation active in the digestive system of animals (Huddleston, 2014; Mercer et al., 1999b; Rizzi et al., 2012), although DNA fragments can persist in the gastrointestinal tract of mammals (Rizzi et al., 2012). Transformation of the microbiota in the lower gastrointestinal tract, including the stomach, small intestine, cecum and colon, of rats has not been detected in experimental studies, even in the presence of high similar DNA (Nordgard et al., 2012).

Some Limitations of the DNA Uptake Model Systems Used

The data generated from transformation assays used to determine the availability and uptake of DNA in bacterial recipients are linked to the specific laboratory conditions employed. The informative value of such data on the DNA uptake processes occurring under natural conditions must be assessed case by case. Some technical constraints often embedded in the studies include the practice of adding bacterial recipients of a single strain, and often also DNA and nutrients, to a laboratory-maintained microcosm under semi-artificial conditions (Ashelford et al., 1997; Pearce et al., 1997). With few exceptions, studies of DNA uptake by natural transformation have been conducted *in vitro*, or in microcosms intended to represent soil, plants, or the gastrointestinal tract. The ability to establish representative bacterial habitat locations and population sizes after introducing externally cultured bacterial recipients into structurally organized microcosm models containing heterogeneously distributed indigenous bacteria is questionable (Bundt et al., 2001; Hallmann et al., 1997; Ranjard and Richaume, 2001). Few, if any, studies have examined DNA uptake processes in indigenous microbial communities with the DNA naturally present and spontaneously released on site. Moreover, the concerted action of DNA uptake and selection in determining the genetic compositions of bacterial populations undergoing adaptation to environmental changes is rarely studied in combination.

Several explanations for the dearth of such studies can be found. Most importantly, the range of gene transfer frequencies that can be practically measured in the laboratory is around 1 transformants per 10^8 – 10^9 exposed cells. The lower relative cell densities of a given species that are usually present in natural bacterial communities effectively limit the gene transfer frequencies that can be measured (Nielsen and Townsend, 2004). Another limitation is that only a fraction of the indigenous bacteria from any given environment can be cultivated for subsequent selection, making DNA uptake difficult to verify in uncultivable bacteria. Moreover, the use of selectable marker genes as a tool for DNA uptake identification is sometimes problematic due to frequently encountered background resistance to most antibiotics and a limited ability of rare transformants to adequately express the marker gene (Nielsen et al., 1998). Only a minor portion of bacteria from any given complex environment is, therefore, susceptible to positive selection by antibiotics and will take part in any screen for competence development. Because most detection methods of DNA transfer in bacteria are based on the uptake of resistance genes, the enumeration procedures usually performed on selective media disturb the sites and conditions that induced the gene transfer. Methods are now being developed for the *in situ* detection of discrete bacterial cells that allow potential DNA uptake events to be identified and quantified *in situ*. For instance, fluorescent protein (eg, green fluorescent protein) markers have been used to monitor horizontal acquisition of genetic material *in situ* (Dahlberg et al., 1998; Rizzi et al., 2008).

Most studies on natural transformation have been performed with monocultures with high population densities of the bacterium grown under laboratory conditions. Transforming bacterial species may, however, have specific requirements for competence development and resource utilization in complex environments. Hence, conditions conducive for gene transfer by natural transformation vary and the conditions established in the laboratory may not be those promoting competence development under natural conditions. For instance, transformation of *P. fluorescens* was not detected under several *in vitro* conditions, while such phenomenon could be observed *in situ* (Demaneche et al., 2001). It, therefore, follows that species currently thought to be nontransformable may show competence under yet unmonitored conditions.

Factors Affecting the Stable Uptake of DNA in Single Bacterial Cells

Molecular barriers define the sexual isolation or the degree to which two bacteria are prevented from exchanging genetic material by recombination. Sexual isolation may be expressed in terms of observed recombination frequencies between two bacteria, or more specifically as the ratio of homogamic recombination within species to heterogamic recombination between species (Majewski, 2001). Moreover, recombination frequency depends on the chromosomal location of the phenotypic marker, rendering sexual isolation between two strains locus-specific (Ray et al., 2009). Molecular barriers act upon chromosomal DNA uptake from its first interaction with the outside of the cell through its integration in a heritable state (Majewski, 2001).

Studies on natural transformation with various degrees of divergent DNA (Table 2) show that low DNA sequence similarity is a strong barrier to the integration of chromosomal DNA in bacteria. Indeed, studies have consistently demonstrated an absolute requirement for sequence similarity for detectable acquisition of chromosomal DNA by homologous recombination (Majewski, 2001). For some bacteria, the minimum length of 100% DNA similarity necessary to facilitate efficient DNA integration has been experimentally determined and is referred to as the minimum efficient processing segment (MEPS) (Matic et al., 1996; Shen and Huang, 1986). The minimum amount of base-pairing required for a single region to initiate heteroduplex formation with linear DNA substrates is 153 bp in *S. pneumoniae* (Prudhomme et al., 2002) and 183 bp in *A. baylyi* (de Vries and Wackernagel, 2002). Fewer details are available for the exact minimum requirements for double-sided DNA similarity for heteroduplex formation to occur. Such quantification is also not straightforward as it is likely to depend on the species and strain, and the specific nucleotide composition (GC%, etc.) of the recombining regions. For circular DNA intermediates (present in double-stranded form in the cytoplasm), DNA similarities of as little as 25 bp can mediate a single-crossover event and integration into the bacterial chromosome (Shen and Huang, 1986).

Base pairing of the single-stranded donor DNA with the complementary recipient strand within the heteroduplex molecule results in the formation of a double-stranded region that is recognized and acted upon both by host restriction modification (RM). Transforming DNA becomes single-stranded during the translocation process, which should theoretically render it insensitive to immediate digestion by restriction enzymes (Majewski, 2001; Matic et al., 1996). Nevertheless, studies indicate that restriction systems can reduce heterogamic transformation in *B. subtilis* (Cohan et al., 1991) and in *P. stutzeri* (Berndt et al., 2003).

The DNA mismatch repair (MR) systems of bacteria contribute to sexual isolation by binding to mismatches in heteroduplex regions formed during DNA-strand invasion, resulting in abortion of heterospecific recombination events. While the contribution of MR to sexual isolation in some bacteria (eg, *E. coli*) is large, it appears to be less important in naturally transformable bacteria such as *B. subtilis* and *S. pneumoniae* (Majewski, 2001). In bacteria, defective MR can lead to increased rates of heterogamic recombination in addition to increased rates of mutation, as cells are unable to identify/repair mismatches in heteroduplex DNA formed during heterologous strand invasion. For instance, inactivation of the *mutS* gene, encoding the protein that recognizes and binds to mismatches, results in about 100-fold increase in heterogamic transformation and recombination with DNA substrates of 24% sequence divergence in *A. baylyi* (Ray et al., 2009), threefold in *B. subtilis* (at 14.5% sequence divergence) (Majewski and Cohan, 1999), and sixfold in *P. stutzeri* (at 14.6% sequence divergence) (Meier and Wackernagel, 2005). These results are in contrast to plasmid-phage recombination systems in *E. coli* or *Salmonella enterica* subspecies Typhimurium, where *mutS* deletions increase heterogamic recombination rates by 1000- to 10 000-fold (Majewski, 2001). Reasons for this dichotomy in MR inhibition of heterogamic recombination are unknown, but it may be due to the molecular machinery of the individual bacterium or due to the nature of DNA interacting with the recipient chromosome (single-stranded in *B. subtilis*, *P. stutzeri*, and *A. baylyi* vs. double-stranded during phage or plasmid integration in *E. coli* and *S. enterica*).

Considerations of the Long-Term Persistence of Horizontally Acquired DNA in Bacterial Populations

The observed frequencies of DNA uptake, and prevalence and diversity of transformants in a bacterial population are determined by (1) the molecular barriers to natural transformation (see above); (2) the limited access to relevant DNA as determined by the nucleotide diversity present and accessible (physical and geographic isolation) (Majewski, 2001); and (3) the reduced fitness of bacterial transformants, after uptake of most random DNA fragments, that could lead to their removal from the bacterial population by purifying selection (Bjorkman and Andersson, 2000; Kuo and Ochman, 2009).

Experimental transformation studies have most often focused on quantifying the frequencies at which particular gene segments may be taken up by bacteria at one or a few chromosomal loci. The DNA uptake rates quantified are often described in the scientific literature as “low” to “high.” It is important to note that such grading only reflects the range of frequencies that can be practically measured in limited sample sizes in the laboratory (Rizzi et al., 2008). The grading is not, as often erroneously implied, linked to the subsequent biological impact of the acquired DNA in the bacterial population. It may be that frequencies below those that can be observed in a 24–48-h DNA uptake experiment in the laboratory are significant in the long run (Nielsen et al., 2014). Most successful HGT events identified through comparative DNA analysis of bacterial genomes are estimated to have occurred over a timescale of millions of years (Croucher et al., 2014; Lawrence and Ochman, 1998). Therefore, experimentally measured DNA uptake frequencies collected over minute timescales in the laboratory may not necessarily provide relevant information to understand the occurrence and biological impact of infrequent DNA uptake events taking place in larger bacterial populations over several years.

In addition to considerations of the relevant timescale of DNA uptake events, the timescale of transformant population expansion may also be considerably longer than what can be practically measured in the laboratory. The long-term fate of any DNA uptake event/transformant is determined by selection and genetic drift and not the DNA uptake frequencies themselves. This is because it is the population trajectories of the descendants of the primary transformants that will determine the long-term survival and impact of the transformant (Thomas and Nielsen, 2005). For instance, single DNA uptake events may take place within the time span of a few bacterial generations. Nevertheless, it may subsequently take many thousands of generations and, hence, many years before the trait will become widespread in the overall bacterial population after clonal division and directional selection of the transformant. The latter process can only be approximated through modelling (eg, probabilistic or deterministic) of bacterial populations, if the strength of the selection of the transformant is known (Moradigaravand and Engelstadter, 2014; Starikova et al., 2012). Additionally, the spatial structure of the populations is important in the prediction of the dynamics of natural transformation (Moradigaravand and Engelstadter, 2014). The timescale needed to understand DNA uptake processes as they occur naturally depends on the objective of the study, the anticipated directional selection of the transformant bacteria, and their population structure, size, and generation time.

Predictors of DNA Uptake in Bacteria and Implications for the Release of Genetically Modified Microorganisms

Genomic information and laboratory evidence support both the occurrence of genetic recombination between bacteria of variable genetic relatedness and the existence of mechanistic and selective barriers that maintain divergence between bacterial lineages. A challenge in microbiology is to reconcile these two observations to assess the recombinogenic potential and impact thereof between different bacterial entities. The ability to accurately predict the potential for two separately evolving bacterial lineages to undergo genetic exchange remains, however, in its “adolescence.” This is illustrated by our inability to predict the impact of future HGT events on bacterial genome evolution, although data on DNA uptake frequencies can be extracted from many experimental model systems. Knowledge of the factors governing horizontal transfer and selection of transformed bacteria is, nevertheless, crucial to the evaluation of the potential for unintended spread of recombinant DNA from genetically modified microorganisms (GMMs) (Keese, 2008). GMMs can offer benefits in, for example, improving food production and utilization and in disease prevention (Aguilera et al., 2013; Gilsdorf and Zilinskas, 2005). A potential hazard arising from the indiscriminate use of GMMs is adverse alteration of indigenous bacterial populations after horizontal transfer of recombinant DNA (recDNA) (de Carcer et al., 2007; De Leij et al., 1995).

Most countries and many international organizations have developed legislation and recommendations on the types of assessments necessary prior to the commercial use of GMMs (Aguilera et al., 2013). For instance, the Codex Alimentarius Commission of the United Nations have developed principles for risk analysis and guidelines for safety assessments of foods derived from modern biotechnology, including recDNA microorganisms (Codex Alimentarius Commission, 2003). In most assessments of genetically modified organisms (GMOs), the starting point is the familiarity and the history of safe use/behaviour/consumption of the parent organism. The concept of “substantial equivalence” is used to structure the assessment relative to the conventional counterpart and to focus the assessment on the determination of similarities and differences. Thus, risk assessment is based on the introduced biological changes in the modified organism and does not usually address the biological safety of the parent microorganism itself (Aguilera et al., 2013; Waigmann et al., 2012). In the context of unintended horizontal transfer of recDNA, some general safety recommendations for the construction of GMMs have been made (Codex Alimentarius Commission, 2003):

1. The genetic modification performed should be limited to the intended trait, and the final GMM or product thereof should not contain unnecessary DNA sequences, for example, antibiotic marker genes, DNA sequences that confer or stimulate genetic mobility of the recDNA, or DNA sequences that can confer or affect pathogenic properties.
2. A chromosomal location of the recDNA is desired because extrachromosomal elements such as plasmids are often self-transferable or mobilizable between cells and species. Plasmids also harbour replication functions that ensure their stability in an extracellular state over bacterial generation.
3. The use of recDNA (genes) that mediate a selective advantage to unintended bacterial recipients should be avoided to prevent dissemination of recDNA in bacterial communities.

The general recommendations made above are precaution-based and seek to minimize both the likelihood of uptake of recDNA in bacterial populations, and the potential positive selection of unintended bacterial transformants carrying recDNA, if rare DNA uptake events occurred. To reduce the likelihood of occurrence of unintended HGT, the recDNA may be inserted into the chromosome in the absence of sequences conferring mobility. Empirical and theoretical data provide a basis for the identification of parameters of importance for limiting the transfer potential of chromosomal DNA between bacteria. Nucleotide differences in DNA sequence between bacterial strains and species are probably the most important barrier to recombination of chromosomal DNA in bacteria (as discussed above). The lack of DNA sequence similarity between the donor and the recipient DNA preclude the ability of the transforming (rec)DNA fragment to form a heteroduplex with the recipient chromosome. In general, experimental studies in transformable bacteria have shown that DNA substrates with more than approximately 30% sequence divergence will not be successfully integrated in the recipient genome. Knowledge of the sequence divergence between species can be a useful predictor of their overall recombination potential. Different approaches are available to estimate the overall DNA sequence similarity between bacteria, including DNA–DNA hybridization, whole genome comparisons, or comparisons of housekeeping genes, including 16S rRNA (Goris et al., 2007; Wayne et al., 1987; Woese, 1987). While predictors of overall genomic sequence relatedness can be useful to understand the potential for chromosomal recombination between species, knowledge of local sequence divergence and conservation in the area spanning the recDNA will more accurately reflect its recombination potential into unintended recipients.

The technical approaches to limit the potential of unintended recDNA transfer from GMM are required because a precise understanding of bacterial fitness of unintended recipients of recDNA is lacking. As discussed above, it is not the transfer frequencies of chromosomal DNA that will cause a biological impact, but directional positive selection of transformants carrying recDNA. Integrated DNA fragments (including recDNA constructs) are likely to cause phenotypic changes that negatively affect the transformant fitness relative to the larger bacterial population and communities. Transformants carrying recDNA that are not competitive in growth and cell division will not remain in the larger bacterial population for long. Identifying conditions that may promote positive selection of transformants is, therefore, essential to understand the fate of recDNA in any bacterial population. The use of recDNA (genes) that is likely to mediate a selective advantage to unintended bacterial recipients should be avoided to prevent unchecked dissemination of recDNA in bacterial communities. Unfortunately, available methodology does not readily facilitate the collection of empirical data on the selection coefficients of GMMs and unintended bacterial recipients of recDNA in agricultural settings or the gastrointestinal tract. Expert evaluation and inference from a history of safe use and expected behaviour (of both the recDNA donor[s] and the recDNA recipient bacterium), therefore, remain an essential component in the case-by-case assessment of GMMs.

Clinical Relevance of HGT and Antibiotic Resistance

The range of pathogenic species that are able to express competence determines the clinical relevance of natural transformation. It was recently demonstrated that genetic diversity is linked with competence (Jorth and Whiteley, 2012), and natural transformation is expected to greatly contribute, together with other HGT mechanisms, to the dissemination of antibiotic resistance determinants and traits (Domingues et al., 2012a, b; Ochman et al., 2000; Roberts and Kreth, 2014). Most often, the intercellular gene transfer mechanism responsible for that pathogenic bacteria acquire new virulence or antibiotic resistance traits remains unknown. This is because all known gene transfer mechanisms are able to transfer chromosomal DNA fragments, plasmids and mobile genetic elements. Moreover, the gene transfer frequencies are alone rarely indicative of the effects (Feil et al., 2001; Pettersen et al., 2005). The acquisition of new genetic traits can transform bacteria from harmless to pathogenic. We now have bacteria that are virtually resistant to all known classes of antibiotics (Magiorakos et al., 2012), such as the ESKAPE (*Enterococcus faecium*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and *Enterobacter* spp.) pathogens (Boucher et al., 2009). The decline in the antibiotics development by the pharmaceutical industry in the last years seems to lead us to a post-antibiotic era, where antibiotics are not effective and the rate of development of new ones is extremely low (Fowler et al., 2014). Alternatives to antibiotics must be considered (Allen et al., 2014).

How Microbial Pathogens Subvert Host Innate Immune Defenses[☆]

The Skin and Mucosae Protect Us From Most Microbes

All organisms must interact with the outside world and regulate two-way communication. Each tissue in contact with the environment has a protective barrier, either skin or mucosa, through which this communication occurs. In addition, the brain, eyes, and testes are encased in specialized membranes to protect them from the rest of the body, including circulating immune cells that can cause damage. The first step to becoming a pathogen is to breach one or more of these barriers.

How Pathogens Cross the Skin

Skin is mainly composed of the epidermis and dermis layers. The outer layer, the epidermis, is made up mostly of cells called keratinocytes that produce the intracellular protein keratin that aids in providing durability. The outermost layer of skin consists of dead cells that form a dry, acidic, and rigid wall covered with chemicals that limit microbial colonization. These chemicals derive from glands producing sweat and sebum or are secreted by keratinocytes. Antimicrobial lipids and peptides from these same sources limit the kind and numbers of microbes that survive on skin. Some of the microbes that can survive on the skin, particularly the bacterium *Staphylococcus aureus*, are commensals that effectively prevent new microbes from finding binding sites through which they could access water and nutrients. Thus, our skin, while warm, is not a welcoming environment for most microbes.

Microbes that cross the skin barrier may do so passively on the surface of a damaging agent, such as gravel, at the time and site of damage. The vast majority of these microbes are not pathogens and are quickly killed by a healthy immune system. Some pathogens passively cross the skin with assistance from an insect or animal. The causative agent of Lyme disease, the bacterium *Borrelia burgdorferi*, is delivered into tissue with saliva via an insect bite. Similarly, animal bites transfer the Rabies virus from saliva of an infected animal across the skin barrier of a victim. In addition to saliva, animal and insect feces can harbor pathogens that are passively transferred across our skin. The eukaryotic parasite that causes Chagas disease, *Trypanosoma cruzi*, is deposited on our skin by the Kissing Bug in feces. When we scratch the site, *T. cruzi* is delivered across the skin barrier through the feces left by the Kissing Bug. These are just a few examples of the many different pathogens of all kinds that cross the skin barrier with assistance from either other organisms or our own actions.

A skin commensal can become a systemic pathogen

A human commensal that normally resides on and protects the skin, *Staphylococcus aureus*, may become a pathogen if it passively crosses the skin barrier. Normally, tissue damage triggers a signaling cascade that recruits neutrophils, immune cells that are expert at killing microbes. However, some *S. aureus* strains appear to benefit from the signaling cascade, including inflammatory cytokines and chemokines that normally protect our damaged skin. These bacteria preferentially colonize inflamed skin, such as a surgical wound, and cause a localized infection that may become systemic. *S. aureus* has even been observed to replicate in the presence of neutrophils and multiple antimicrobial chemicals we produce that normally inhibit bacterial survival. The molecular mechanisms by which *S. aureus* exploits our inflammatory signaling to colonize wounds require further understanding to facilitate the development of new treatments.

The Mucosal Barrier is a Key Host Defense

Mucosal tissues are more involved in communication with the environment than the skin. These tissues exchange water, light, gasses, nutrients, waste, pheromones, and gametes with the environment, and can be found in the airway, urogenital tract, and eyes. Conditions that allow for exchange also expose mucosal surfaces to large numbers of diverse microbes. We protect our mucosa with an aqueous and/or fatty acid layer: tears, saliva, mucus. Mucus is constitutively produced by specialized cells in the mucosal epithelium, such as the goblet cells of the gut. In response to stress or damage, the volume of mucus that we generate increases rapidly. Most microbes are limited to the surface of a mucous layer due to the high viscosity and an abundance of antimicrobial chemicals and peptides contained in the mucus. The vast majority of these microbes are not pathogenic and help defend the host from pathogens, for instance, by simply taking up physical space and by efficiently utilizing available nutrients.

[☆]Change History: December 2018. JL Dombach and CS Detweiler have made minor changes in the Text and the References.

This article is an update of M. Rhen, S. Normark, M.W. Hornef, Subversion of Host Defences by Microbes, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 748–758.

Crossing the mucosal barrier

Pathogens use a number of strategies to cross the mucous layer. The bacterial pathogen *Helicobacter pylori* swims through gastric mucus toward the underlying epithelium using flagella. Further down the gastrointestinal tract, the eurytopic protozoan pathogen, *Entamoeba histolytica*, forges a path through colon mucus by secreting proteases that cleave mucins, a major saccharide component of mucus. Mucus also contains a potent host protease, lysozyme, which degrades bacterial cell walls. The bacterium *Listeria monocytogenes* fights back by chemically modifying peptidoglycan, a key component of the cell wall, to be less sensitive to lysozyme. This reduction in lysozyme sensitivity enables *L. monocytogenes* to survive transit through the mucous layer and to subsequently live within macrophages.

Changing the local environment to outcompete other microbes

Pathogens can outcompete commensals using molecular tricks to make the environment more beneficial for them. One major pathogen strategy is to change the host environment in a manner that benefits the pathogen and restricts commensals. For instance, when *Salmonella enterica* serovar Typhimurium colonizes the intestine, it stimulates inflammation. Incoming inflammatory cells and fluids radically change the intestinal environment in a manner that *Salmonella* has evolved to exploit. In particular, *Salmonella* takes nutritional advantage of the availability of a different set of electron acceptors and carbon sources, enabling the pathogen to out-grow commensals.

Binding to Host Cells and Surviving Host Defenses at the Epithelium

When a pathogen finally reaches the epithelial layer, it needs to adopt new strategies to survive. One strategy is to adhere to epithelial cells. Bacteria use pili, long thin protein filaments that extend out from the bacteria to reach epithelial cells. At the ends of pili are proteins called adhesins that bind to specific host cell surface proteins. Another trick microbes use to attach to the surface of an epithelial cell involves inserting their own adhesive protein into the host cell membrane. For instance, some pathogenic *Escherichia coli* use a secretion system to inject a bacterial protein directly into the membrane of a host cell. *E. coli* then uses a protein on its own cell surface to bind the target protein it has just placed on the host membrane.

Mammals defend themselves against bacterial adherence to epithelial cells by increasing the turnover rate of these cells, a process that leads to more rapid shedding of the microbe back into the mucosal lumen. In turn, some microbes have evolved mechanisms to slow down the division rate of the stem cells within our intestine that divide to replace shed epithelial cells. This benefits the microbe by increasing the time it has to reside at the epithelial layer, before either breaking through this layer or being shed back into the lumen.

Breaking Through the Epithelial Layer

Pathogens use diverse molecular strategies to cross the host epithelial layer. Some microbes translocate across epithelial cells. This process does not typically damage the epithelial cell, as the pathogen can engineer its own uptake from the lumen or apical side of the epithelial cell within a host vesicle. This vesicle, called a phagosome, is transported via the cytoskeleton and motor proteins across the epithelial cell to fuse with the membrane on the basal side, releasing the pathogen. Another way to cross the barrier involves secreting proteins into the host cell that disrupt the tight junctions between epithelial cells. For example, the bacterium *Vibrio parahaemolyticus* delivers a protein to the host cytoplasm that modifies a host protein (i.e., catalyzes the covalent addition of AMP to Rho GTPases). Modifying the host protein leads to the disruption of the actin cytoskeleton and the rounding of the epithelial cells such that the bacterium can cross over. Alternatively, microbes such as *Vibrio cholerae* secrete a protease which cleaves the extracellular domain of a host tight junction protein to allow for the bacterium to pass between cells (Fig. 1).

A more dramatic way to cross the epithelium is for a microbe to either kill or exploit the death of an epithelial cell, and then pass through the gap before other cells migrate into the area to seal the break. However, the death of an epithelial cell typically alerts the immune system, radically changing the local biology in a manner that may benefit or harm the pathogen. Microbes can alternatively cross the epithelial layer in a manner that exploits the immune system but does not cause outright tissue damage: within a professional phagocyte. Dendritic cells are a type of professional phagocyte that is noted for reaching cytoplasmic projections called podia between the tight junctions of epithelial cells into the mucosal lumen, capturing microbes, and then retracting podia and pathogens back through the tight junctions to the basal side of the epithelium. The microbe then has to either be able to survive within, or kill and escape from, the professional phagocyte.

At least one microbial pathogen has been reported to use as many as three of the methods outlined above to cross the epithelial barrier. After adhering to host cells, the yeast fungal pathogen *Cryptococcus neoformans* transcytoses across epithelial cells, either causing or exploiting the death of the epithelial cell and thereby gaining access to the basal side, or is captured by a professional phagocyte that takes the microbe across the epithelial barrier without damaging host cells.

Underneath the Epithelial Barrier—The Lamina Propria

Mucosal tissue is underlain by the lamina propria, an area of loose connective tissue in which cells of the innate and adaptive immune systems coordinate responses to damage caused by pathogens. Underneath the lamina propria is a layer of smooth muscle that contracts regularly to keep fluids moving through our mucosal tissues. Smooth muscle also causes the involuntary contractions

Fig. 1 Two ways pathogens cross mucosal barriers: translocation and dendritic cell. (A) The layers of the mucosae. First pathogens must cross a layer of mucus that is highly viscous because it is made up of mucins and is toxic to bacteria because it contains the host protease lysozyme, which degrades bacterial cell walls. Some bacteria cross the mucus layer by using their flagella. Once past the mucus, the pathogen must then cross the epithelial layer to reach the lamina propria. (B) Some pathogens are taken up by epithelial cells and then translocated across the cytosol to the basal layer in a phagosome. The phagosome is then brought to the basal side of the epithelial side by the cytoskeletal actin filaments (blue). Once the phagosome reaches the basal side, it fuses with the cell membrane and releases the pathogen into the lamina propria. (C) Pathogens can cross the epithelial layer by being taken up by the podia of dendritic cells (DC) that has inserted itself between epithelial cells. The podia then retracts, bringing the pathogen with it.

that suddenly force mucus out of the body, through a sneeze, for instance. Ideally, any pathogens residing in the tissue are expelled along with the mucus.

Avoiding, Evading or Destroying Host Soluble Defenses

Molecular defenses that are soluble are present all over the body, including on the skin and in mucus, in all tissues, blood, and interstitial fluid. Defenses such as complement, antimicrobial peptides (AMPs), and molecules that sequester nutrients from microbes are crucial for innate immunity and form a bridge to adaptive immunity. In addition, multiple aspects of adaptive immunity that are soluble are outlined below.

Complement

Complement is a host defense system that tags bacteria for recognition and engulfment by professional phagocytes, or, for recognition by a series of proteins that create holes in bacterial membranes, a process called the Membrane Attack Complex (MAC). Many microbes such as *E. coli*, defend themselves against complement by secreting saccharides which assemble into an exterior coat that makes it difficult for complement proteins to bind the pathogen surface. Before complement proteins can bind a bacterial surface, they have to trigger a proteolytic cascade that serially activates the proteins that will tag the microbe. Pathogens have evolved to disrupt this cascade, for instance, by secreting proteases that inactivate critical steps. Inactivation of critical steps effectively prevents the pathogen from being tagged and then recognized by a phagocyte. Some pathogens alternatively capture serum host proteases that cleave the tag attached to the bacterial surface. These host proteases evolved to protect host cells from complement, which deposits indiscriminately on friend and foe. When a pathogen hijacks a host protein to destroy the complement tag on the bacterial surface, the pathogen is effectively protected from recognition by a phagocyte and from the subsequent molecular steps that would allow for the MAC to assemble. For instance, *Neisseria gonorrhoeae* evades complement by using their pili to capture host anticomplement factors, such as the CD46 protein, and transport them to the bacterial membrane for protection. These are just a few of the many ways by which microbes evade recognition by the host complement system (Fig. 2).

Antimicrobial Peptides (AMPs)

AMPs are a diverse group of molecules present in all body fluids, including the fluids that bathe mucosal tissues. These peptides are typically positively charged and thereby able to interact electrostatically with the negatively charged surface of bacteria, fungi, and viruses to cause membrane damage and often destroy the microbe. Microbes detect membrane stress caused by AMPs and respond in multiple ways. For example, since many AMPs are cationic, microbes typically alter their surface charge to repel AMPs. For Gram-negative bacteria, this involves modifying the lipopolysaccharide (LPS) in the outer leaflet of the outer membrane. Gram-positive

Fig. 2 Pathogens escape host complement using various methods. (A) Some bacteria excrete saccharides that inhibit the binding of host complement proteins to the bacterial membrane. (B) Pathogens can capture host proteases that are present in serum to prevent host cells from being tagged for complement. Through the use of the host protease the complement protein is cleaved and the pathogen has escaped recognition by complement.

bacteria modify their cell wall lipo teichoic acids (LTA) to evade AMPs. Both kinds of bacteria induce expression of enzymes that modify their surfaces, by adding or removing chemical groups to LPS or LTA. A second strategy for dealing with AMPs is to cleave them with secreted proteases and thereby detoxify them. Microbes also sequester AMPs to prevent them from reaching the bacteria. For example, Gram negative bacteria release outer membrane vesicles that trap AMPs in the extracellular environment. Microbes also simply export AMPs out of the cytoplasm or periplasm using efflux pumps, an energy intensive process. More recently, the role of biofilms in microbial protection from many kinds of toxic molecules including AMPs has been described. Since biofilm formation requires a critical mass of microbes and often includes microbes from multiple kingdoms or species, it is a good example of the role of social behavior in evading host defenses.

Biofilms

Biofilms are complex structures that consist of microbial cells, from one or multiple species of bacteria or fungi, that adhere to a surface. The microbes within the biofilm are embedded in an extracellular matrix mainly composed of polysaccharides and proteins produced by the bacterial cells, as well as extracellular bacterial DNA. This matrix provides support to cells in the biofilm, as well as increased protection from the environment. Many microbial species form biofilms during infection to evade harsh environments, antibiotics, and/or host defenses. One species that forms a biofilm to evade antibiotics, as well as host defenses, is the bacterium *Staphylococcus epidermidis*. *S. epidermidis* usually resides on the skin as a commensal, but has recently become a common nosocomial, or hospital acquired, infection. *S. epidermidis* enters through wounds but lacks virulence factors like *S. aureus*, and because of this *S. epidermidis* only colonizes a host when it has formed a biofilm on implanted medical devices. In addition to holding the biofilm together, the major polymer in *S. epidermidis* biofilms increases bacterial resistance to AMPs. Recent evidence also shows that some strains of *S. epidermidis* produce an enzyme that activates biofilm formation, as well as proteases that target neutrophils, and may use the cleaved neutrophil products as part of the biofilm matrix (Fig. 3).

Nutritional Immunity

Body fluids and mucus contain host defense molecules aimed at depriving microbes of specific nutrients. The best studied mechanisms deprive microbes of metals, such as iron and zinc, that are essential cofactors for enzymes. To ensure that cells have the cofactors they require, bacteria produce proteins called siderophores that capture local iron or other essential metals and deliver them to the bacteria. However, hosts can produce proteins that inhibit siderophores from functioning. For instance, once *Salmonella* infects a human gut, a cascade of signals triggers inflammation of the gut as well as the production of host proteins which bind and inactivate siderophores, thereby inhibiting bacterial acquisition of iron and zinc which are required for various essential metabolic activities. These host proteins are not specific to siderophores of pathogens, thus commensal species are also targeted. However, *Salmonella* has evolved a mechanism so that its siderophore is not bound by these host proteins, allowing the siderophore to bind iron and be taken up by *Salmonella* for its metabolism. Because commensal organisms often cannot compete with the host to acquire essential cofactors, the ability of *Salmonella* to modify its siderophore in this environment gives it a competitive advantage over commensals. In addition to metal sequestration, *Salmonella* is able to take advantage of the inflammation that is triggered by its

Fig. 3 Some species, like *Staphylococcus epidermidis* form biofilms to evade host defenses. To form a biofilm *S. epidermidis* produces numerous proteins and polymers. To initiate biofilm formation *S. epidermidis* must express the proteins AltE and Fbe which aid in attachment of the cell to the substrate. The surface protein Aap must be made and activated by cleavage. Once cleaved, Aap promotes interactions between *S. epidermidis* cells. Many strains also produce the polymer PIA which aids in holding cells together in the biofilm. As the biofilm matures extracellular DNA becomes stuck the biofilm matrix, which provides further structure. The coating of cells in the biofilm matrix protects them from many host defenses such as AMPs, as well as antibiotics.

presence in the gut. Inflammation changes the nutrients and potential electron acceptors that are available in the environment. Unlike most commensals, *Salmonella* is able to use this set of nutrients and electron acceptors giving it an additional advantage and allowing it to grow and outcompete commensals (Fig. 4).

Residing in Tissues Protected From the Immune System

Some microbes are able to evade host defenses by escaping to organs, such as the brain or the eyes, where immune cells are not normally present because an endothelial membrane barrier keeps them out. *Toxoplasma gondii* is an obligate intracellular, eukaryotic

Fig. 4 *Salmonella enterica* acquires essential nutrients in the host gut. (A) Commensal bacteria in the gut of mammals produce siderophores to capture iron and bring it back to the bacterial cell to be used as essential cofactors by enzymes. (B) Upon colonization of the host by *Salmonella* the gut becomes inflamed and proteins are produced that bind bacterial siderophores inactivating them. *Salmonella* is unaffected by these proteins due to a sugar modification on their siderophore that inhibits recognition by host proteins. Because commensal siderophores are affected, but siderophores of *Salmonella* are not, *Salmonella* is able to acquire iron and thrive.

parasite that can cross the barrier that protects the brain, the blood–brain barrier (BBB). *Toxoplasma* is spread to mammals through contaminated cat feces. Once ingested, the parasite quickly replicates and is targeted by the immune system. However, as infection progresses *T. gondii* transitions into a slowly replicating form that becomes enclosed in a cyst. In humans and rodents this transition to the encysted form occurs in the brain. To enter the brain *T. gondii* must cross the BBB which is responsible for keeping out pathogens and immune cells. *T. gondii* can use three different methods to cross the BBB. Unlike many organisms that use flagella for swimming motility, *T. gondii* uses cytoskeletal motors to propel itself forward in a gliding manner. Using its gliding motility, *T. gondii* is able to move across the endothelial cell barrier of the BBB by gliding between cells. Another method is to bind to endothelial cells and be taken up by the cell. Inside the endothelial cell the parasite replicates and is then lysed out on the basal side, adjacent to the brain. The final method to cross the BBB is by infecting an immune cell which then crosses the layer of endothelial cells in the BBB. While immune cells cannot normally cross the BBB, research has shown that both macrophages and dendritic cells can cross the BBB after infection by *T. gondii*, and that *T. gondii* likely uses these cells to cross the BBB. Recent work has shown dendritic cells exhibit a hypermotility phenotype when infected with *T. gondii* and that this hypermobility may aid in crossing the BBB.

Soluble Adaptive Immunity—Antibodies

Each of the defenses listed above are considered elements of the innate immune system, which is active at all times but increases in strength the moment a host detects a pathogen, or damage caused by the pathogen. A major function of the innate immune system is to induce adaptive immunity, which generates specific responses to the invading pathogen. While the adaptive immune system is beyond the purview of this article, a key aspect of adaptive immunity, once generated, functions very much like innate immune system components, particularly complement, and therefore is briefly described. Adaptive immune cells (B cells) produce *antibodies*, large soluble proteins that circulate until they bind to pathogens. Antibodies effectively tag pathogens and mark them for capture and destruction by host phagocytic cells and are in this way conceptually analogous to complement. Complement and antibodies work together during an infection, and even on the same bacterium, to ensure that pathogens are rapidly cleared.

Host Cellular Defenses

The classic cellular players of innate immunity are professional phagocytes, largely consisting of neutrophils and macrophages. In addition, NK cells are now recognized to be critical to defending the host prior to the full activation of adaptive immunity. For these reasons, pathogens have evolved strategies to avoid or thwart each of these cell types.

Avoiding Phagocytosis

While the bacterium *Staphylococcus aureus* is generally a human commensal (see above), when it becomes pathogenic it employs numerous methods previously described to evade host defenses such as resistance to AMPs and lysozyme. However, *S. aureus* also has a mechanism to avoid phagocytosis. The cell wall of *S. aureus* has protein A anchored into it. Protein A is known to bind host antibodies (IgG) that would target the cell for phagocytosis. However, when IgG binds to protein A, it is bound in an orientation that neutrophils cannot recognize, allowing the cell to escape phagocytosis.

Inactivating and/or Adapting to the Phagosome

Some bacteria are able to evade the immune system by living and replicating within the phagosome. For example, the bacterium *Mycobacterium tuberculosis* is taken up by macrophages in phagosomes and is able to replicate inside. Under normal conditions a phagosome would recruit vacuolar H⁺ ATPase to acidify the phagosome and then fuse with the lysosome. However, *M. tuberculosis* contains many proteins that inhibit acidification of the phagosome and fusion with the lysosome. For instance, the *M. tuberculosis* cell wall protein CpsA has been shown to inhibit degradation by the lysosome and the protein PtpA has been shown to permeate the phagosomal membrane and bind a subunit of the host vacuolar H⁺ ATPase. After PtpA binds, the H⁺ ATPase cannot bind the phagosome and thus inhibits the acidification of the phagosome and fusion with the lysosome.

Escaping the Phagosome to Live in the Cytosol

Some organisms are able to escape the phagosome and replicate in the cytoplasm of macrophages. The bacterium *Listeria monocytogenes* escapes the phagosome by lysing it through the production of the toxin listeriolysin O (LLO) and lipases. Once outside the phagosome the bacterium replicates in the cytoplasm. In addition to being phagocytosed by macrophages, *L. monocytogenes* can be taken up by epithelial cells where they can also reach the cytoplasm to replicate. To further evade host defenses, *L. monocytogenes* produces a protein that hijacks the host cell cytoskeleton to form actin filaments that propel the bacterium into membrane/vacuolar protrusions and then into the neighboring cell. Once in the neighboring cell, *L. monocytogenes* lyses the vacuoles releasing bacterial cells into the cytoplasm without ever coming into contact with the extracellular environment. In the cytosol, *L. monocytogenes* evades host defenses such as complement and antibodies and further promotes infection by altering how organelles function to promote infection (Fig. 5).

Fig. 5 *Listeria monocytogenes* evades host defenses by surviving in the cytosol of host cells. *L. monocytogenes* enters host cells through a phagosome. Once inside the host cell, *L. monocytogenes* produces lipases and the toxin lysteriolysin O (LLO) to degrade the phagosome membrane and escape into the cytosol. In the cytosol, the bacteria replicates and expresses the protein ActA. ActA interacts with the host complex Arp2/3 to polymerize actin filaments to push the *L. monocytogenes* cell into the neighboring host cell without coming into contact with the extracellular environment. Once in the new host cell, the cycle can repeat.

Nonmammalian Hosts: Evading Plant Defenses

Microbes have evolved methods to evade not only mammalian hosts, but also plant hosts. Plants do not have immune cells that circulate throughout the organism like mammals and must instead rely upon the innate immunity of each cell, and proper systemic signaling to occur from wound sites through which pathogens enter. Like mammals, plants use transmembrane receptors to recognize potential pathogens. When a plant receptor recognizes a microbe by its microbe-associated molecular pattern (MAMP) it can trigger an immune response. However, if a pathogen successfully evades recognition, it will produce effector proteins that can have a wide range of functions, but overall contribute to virulence. In addition to receptors that recognize MAMPs, plants also have a set of receptors that recognize a wide variety of pathogen effector proteins, leading to the activation of immunity. To avoid being recognized by plant receptors, microbes are continually evolving their effector proteins by acquiring mutations or additional effectors. Similar to mammals, once an immune receptor recognizes a potential pathogen, a signaling cascade occurs that will result in a range of responses to get rid of the pathogen, such as production of reactive oxygen and nitrogen species, calcium fluxes, or antimicrobial peptides. However, in addition to this immune signaling pathway, plants use small compounds such as the plant hormones jasmonic acid and ethylene to modify their immune response. As of now, there is no known similar mechanism in the immune response of mammals.

The most successful plant pathogens use numerous methods to evade the plant immune response. The bacterial pathogen *Pseudomonas syringae* has evolved many methods to get around the plant immune system. Of the 60 strains that have been identified, all have been found to use a type 3 secretion system (T3SS) to inject effector proteins that block plant receptors from identifying *P. syringae*, thus escaping degradation. Other effector proteins of *P. syringae* have been shown to inhibit immune signaling by interacting with the host cytoskeleton and prevent signaling molecules from getting to their proper destination. Some strains of *P. syringae* produce toxins and enzymes to degrade host cell walls, or are even able to produce compounds that mimic plant hormones to interfere with immune signaling. This variety in mechanisms to evade the plant immune system is likely why *P. syringae* can infect most crop species and is one of the most common plant pathogens.

Fungal Pathogens and Fungal Infections in Humans

Fungi are eukaryotic microorganisms that are classified traditionally and morphologically into yeast and filamentous forms. Fungi, however, are often pleomorphic and the human fungal pathogens have been categorized into three groups: the yeast, filamentous, and dimorphic fungal pathogens (Figure 1). Dimorphic fungal pathogens exhibit a filamentous (hyphal) form at ambient temperatures below 37 °C and a yeast form at temperatures above 37 °C, during human infection. Dimorphic fungi tend to be restricted to specific geographic regions and are responsible for so-called endemic mycoses. This probably reflects adaptation of the filamentous fungi to certain climates or soils rather than mammalian hosts.

Fungi are responsible for a wide spectrum of diseases in humans, ranging from acute, self-limiting pulmonary manifestations and superficial infections in immunocompetent hosts to life-threatening invasive infections, especially among immunocompromised or hospitalized individuals with serious underlying diseases. Invasive fungal infections are usually severe, involving infections of the blood, deep tissues, and organs. In the past three decades, these infections have emerged as a major cause of human diseases. Most fungal pathogens of humans are ubiquitous in the environment and humans are exposed by inhaling spores. Yet, others are components of the normal human flora and take advantage of immune disequilibria to cause infection. This article will survey the fungal pathogens responsible for invasive human infections, distinguishing those causing opportunistic infections from those responsible for endemic infections.

The opportunistic invasive fungal infections that occur in immunocompromised or weakened hosts almost always represent health care-associated infections and may be either of nosocomial origin, occurring upon hospitalization, or community acquired. The prevailing agents of opportunistic mycoses are *Candida* spp., *Aspergillus* spp., *Cryptococcus neoformans*, *Pneumocystis jirovecii*, and several species of Mucorales (Figure 1). On the other hand, endemic mycoses are due to fungi restricted to specific geographic regions constituting their natural habitat. In contrast to opportunistic pathogens, these fungi also may infect and cause invasive diseases in immunocompetent individuals. Yet, these infections are exacerbated in individuals whose host immune functions are compromised or suppressed. The main pathogens recognized as agents of endemic mycoses are *Histoplasma capsulatum*, *Blastomyces dermatitidis*, *Paracoccidioides brasiliensis*, *Coccidioides immitis*, *Sporothrix schenckii*, and *Penicillium marneffei*.

Opportunistic Fungal Infections

The frequency of invasive infections due to opportunistic fungal pathogens has increased drastically during the recent years. This is in particular due to a growing population of immunosuppressed patients, including hospitalized patients, especially those from the intensive care unit; stem cell and solid organ transplant recipients; patients treated with immunosuppressive treatments; those showing advanced human immunodeficiency virus (HIV) infections or other acquired immunodeficiency conditions; and patients with organ failure syndromes (Alangaden, 2011; Pfaller and Diekema, 2007). Opportunistic fungi are a continuously evolving pathogen group that plagues these vulnerable patients (Figure 1). In hospitalized patients with serious underlying diseases, a number of fungi, including yeasts and filamentous fungi, may cause nosocomial invasive infections, *Candida* spp., *Aspergillus* spp., and species of Mucorales being the most prevalent pathogens (Perlroth et al., 2007; Pfaller and Diekema, 2010; Alangaden, 2011; Lass-Flörl, 2009). In contrast, infections due to *P. jirovecii* and *C. neoformans* are community-acquired infections resulting from the inhalation of aerosolized fungi from the environment (Catherinot et al., 2010; Park et al., 2009).

Infections Due to *Candida* Species

Candida spp. are ubiquitous yeasts commonly isolated from the environment. Current taxonomies list almost 200 species of ascomycetous, asexual yeasts in the genus *Candida*. Among these, a few are encountered in the commensal flora of human beings (Calderone, 2002). *Candida albicans* and other *Candida* spp., such as *Candida glabrata* or *Candida tropicalis*, may be present in the normal gastrointestinal and genital flora of healthy humans, while *Candida parapsilosis*, *Candida famata*, and *Candida guilliermondii* are commensals of the skin.

Candida spp. are opportunistic pathogens that have the ability to cause various superficial and systemic infections when the host's resistance to infection is impaired locally or systemically. The most frequent clinical manifestations are superficial candidiasis, including cutaneous, oropharyngeal candidiasis, and vulvovaginitis. These infections are frequent and usually benign in immunocompetent hosts. *Candida* sp., however, also can cause life-threatening infections, mainly in hospitalized hosts. Neutropenia, neutrophil dysfunction, parenteral nutrition, and disruption of mucosal barriers are the main risk factors for disseminated

Figure 1 Examples of major morphological aspects seen in opportunistic fungal pathogens of humans. (a) Morphology of *Cryptococcus neoformans* in culture and (b) using India ink staining that allows easy visualization of the capsule. (c) Morphology of *Aspergillus* spp. in culture and (d) microscopic feature of *Aspergillus* spp. Lactophenol cotton blue staining shows spores that grow in chains from phialides that emerge from a central vesicle. (e) Morphology of *Pneumocystis jirovecii* upon direct microscopic examination using Grocott's methenamine silver stain (Grocott) and (f) Giemsa stain. (g) Morphology of *Lichtheimia ramosa* in culture and (h) in direct microscopic examination. Lactophenol cotton blue staining shows a globose intact sporangium with sporangiospores.

infections; translocation from the gastrointestinal tract and intravascular catheters are the two main portals of entry for disseminated *Candida* infections. These infections have emerged as a major cause of infectious complications in hospitalized patients with severe underlying diseases, as well as those with complicated surgical abdominal procedures or critical illnesses that need aggressive diagnosis or treatment procedures. Recent and comprehensive epidemiological surveys have reported that infections due to *Candida* spp. account for approximately 75–88% of all nosocomial invasive fungal infections (Aziz et al., 2012; Jarvis, 1995; Perlroth et al., 2007). Notably, *Candida* spp. rank fifth among microorganisms causing nosocomial bloodstream infections in US and European hospitals and *C. albicans* is the most frequently isolated species (Gudlaugsson et al., 2003; Lass-Flörl, 2009; Pfaller and Diekema, 2007; Bougnoux et al., 2008). Invasive *Candida* infections remain associated with a dramatically high mortality, in the range of 40%, despite progresses in their diagnostics and therapeutic advances (Andes et al., 2012; Pfaller and Diekema, 2007). Recent studies suggest a possible improvement of the patient outcomes depending on therapeutic management strategies. In particular, early antifungal treatment has been associated with an improved overall response, suggesting that therapy was more efficient when the fungal burden was low (Garey et al., 2006; Pfaller and Diekema, 2010; Morrell et al., 2005).

Infections Due to *Aspergillus* Species

Aspergillus spp. are filamentous fungi belonging to the Ascomycota phylum. More than 250 species within the genus *Aspergillus* have been described to date (Geiser et al., 2007). Currently, the genus *Aspergillus* is divided into seven subgenera that are subdivided into several sections composed of related species. Most *Aspergillus* spp. have asexual reproduction, but a sexual form has been identified for some of them (Figure 1(c) and 1(d)). These fungi, which are soil saprophytes, play a significant role in the decomposition of organic materials, recycling environmental carbon and nitrogen. During asexual reproduction, abundant conidia are produced and released into the atmosphere allowing the fungi to spread within the environment.

Exposure to *Aspergillus* conidia in the environment may cause a large spectrum of diseases related to host factors, including allergic manifestations, chronic necrotizing aspergillosis, and invasive infections (Figure 2(d) and 2(e)). Although *Aspergillus* conidia spread in the air are from several species, relatively few species are known to cause disease in humans. *Aspergillus fumigatus* is the leading etiological agent of aspergillosis followed by *Aspergillus flavus*, *Aspergillus niger*, *Aspergillus terreus*, and *Aspergillus nidulans*.

In immunocompetent individuals, *Aspergillus* species can induce allergic responses, such as sinusitis and asthma. It might be the consequence of an immune reaction to the colonization of airways by *Aspergillus* spp. in patients who are likely atopic. Allergic

Figure 2 Appearance of Mucorales, *Cryptococcus neoformans*, and *Aspergillus* spp. in infected tissues using the two major stains used to detect fungi histopathologically, Periodic acid-Schiff's stain (PAS) and Grocott's methenamine silver stain (Grocott). (a) Lung infection due to Mucorales. Grocott staining of a lung biopsy shows the fungi stained in black ($\times 100$). (b) Further magnification ($\times 400$) shows the typical structure of Mucorales hyphae in tissue: distorted, nonseptate, and broad hyphae with right-angle branching. (c) Infection due to *Cryptococcus neoformans*. Nodular biopsy shows granulomatous reaction to fungus with 'empty' lacunar spaces containing rounded fungal organisms stained in bright red with PAS ($\times 400$). The cryptococcal capsule is not colored. (d) Lung infection due to *Aspergillus* spp. Grocott staining of a lung biopsy shows the fungi stained in black ($\times 100$). (e) Further magnification ($\times 400$) shows the typical structure of *Aspergillus* hyphae with dichotomous 45-angle branching.

bronchopulmonary aspergillosis is a severe allergic disease that occurs in 1–2% of the patients with asthma and in 1–15% of the patients with cystic fibrosis (Stevens et al., 2003). *Aspergillus* spp. also can proliferate within a preformed cavity in the lungs of patients who are immunocompetent, generating a fungal mass, called aspergilloma. Prevalence of aspergillomas may be high in post-tuberculous cavities and in patients with bronchiectasis or lung abscess.

Acute invasive aspergillosis is a rapidly progressing, often fatal disease that occurs in highly immunocompromised patients. Invasive pulmonary aspergillosis (IPA) is a common infectious complication and a major cause of severe morbidity and mortality in patients with hematologic diseases (Bougnoux et al., 2011). IPA is the leading form of invasive fungal infections in hematopoietic stem cell transplant patients, accounting for 43% of invasive fungal infections (Kontoyiannis et al., 2010). Invasive aspergillosis is confined mostly to the lungs, but sinus and the central nervous system also may be affected. The main defects in host defenses strongly associated with an increased risk for IPA are (1) prolonged neutropenia, (2) qualitative defects in phagocyte function, and (3) deficit in cell-mediated immunity (Patterson et al., 2000; Segal, 2009). Absolute neutrophil count $<100\text{ mm}^{-3}$ and a duration >10 days of neutropenia are major risk factors for IPA. Despite the availability of new antifungal agents, mortality rates range from 30 to 50% (Herbrecht et al., 2002; Neofytos et al., 2010, 2009). Several factors, including the severity of the immunodeficiency secondary to the underlying disease and its treatment, contribute to this extremely poor outcome.

Infections Due to Mucorales

The fungi of the order Mucorales (class Zygomycetes) are filamentous fungi, ubiquitous in decaying soil and vegetation. The pathogenic Mucorales in humans include approximately 10 genera, the most common being *Rhizopus*, *Lichtheimia* (formerly known as *Absidia*; Figure 1(g) and 1(h)), *Mucor*, and *Cunninghamella*. Most human infections result from the inhalation of fungal spores released in the air or from direct inoculation of organisms into disrupted skin. These infections, referred to as mucormycoses, occur mainly in immunocompromised or diabetic patients (Petrikos et al., 2012). The importance of these opportunistic fungal infections has risen in the past few years, as the number of patients with predisposing factors for mucormycosis (e.g., diabetic ketoacidosis, hematologic malignancy, renal failure, and corticosteroid or deferoxamine therapy) has increased dramatically.

Mucorales species are vasotropic, with the hyphae invading blood vessels during infection and causing tissue infarctions and necrosis. The mucormycosis spectra encompass cutaneous, rhinocerebral, and pulmonary infections as well as disseminated infections (Figure 2(a) and 2(b)). Despite antifungal therapy associated with surgical debridement, the overall mortality rate for mucormycosis is extremely high, especially in immunocompromised hosts, ranging from 50 to 100% (Spellberg et al., 2005).

Many other opportunistic filamentous fungi have been reported to be responsible for invasive infections in immunocompromised patients, especially those with hematologic diseases and solid organ transplant recipients. Filamentous fungi, such as *Fusarium* spp., *Scedosporium* spp., or *Geosmithia argillaceae*, give rise to refractory infections in part due to their poor susceptibility to the available antifungal agents (Caira et al., 2008; Valentin et al., 2012; Kontoyiannis et al., 2004).

Infections Due to *C. neoformans*

Cryptococcus spp. are encapsulated yeasts from the Basidiomycota phylum (Figure 1(a) and 1(b)). Two species can cause infections in humans: *C. neoformans* and *Cryptococcus gattii*. *Cryptococcus neoformans* is an environmental species from tree and plants isolated worldwide. Pigeons are known to contribute to its propagation and spread (Mitchell and Perfect, 1995). *Cryptococcus gattii* differs significantly in its geographic distribution and ecologic niches. It is found mostly in tropical and subtropical regions and is associated with Eucalyptus trees. Since an outbreak of *C. gattii* occurred in North America about 12 years ago, however, it has become evident that this species also can be isolated from other environmental samples and in temperate regions (Datta et al., 2009). Cryptococcosis is a lifethreatening infection usually acquired by inhaling aerosolized cells of *C. neoformans* or *C. gattii*. Cryptococcal pneumonia can be the initial form of the disease, but meningoencephalitis is the most common and serious clinical presentation (Figure 2(c)). Cryptococcosis due to *C. neoformans* occurs only in immunocompromised patients, whereas those due to *C. gattii* occur more often in immunocompetent hosts. *Cryptococcus neoformans*, the most prevalent species, causes an estimated 1 million cases of meningoencephalitis globally per year, in patients with acquired immunodeficiency syndrome (AIDS), leading to approximately 625 000 deaths (Park et al., 2009). Administration of highly active antiretroviral therapy (HAART) has resulted in a decrease in the number of cases of AIDS-related cryptococcosis in industrial countries. In developing countries where HAART is not readily available, however, *Cryptococcus* remains a major concern. Other patients at particular risk for Cryptococcal infections include those with neoplastic disorders, mainly Hodgkin lymphoma, those receiving corticosteroids, organ transplant, or immunosuppressive therapy. Cryptococcosis is currently the third most common invasive fungal infection in organ transplant recipients (Neofytos et al., 2010; Pappas, 2010; Pappas et al., 2010).

Infections Due to *P. jirovecii*

Pneumocystis spp. are classified within the phylum Ascomycota, in a unique class, order, and family (Pneumocystidomycetes, Pneumocystidales, and Pneumocystidaceae, respectively) (Redhead et al., 2006). These are atypical fungal microorganisms unable to grow *in vitro* in culture media, thus greatly complicating their study. *Pneumocystis* is ubiquitous throughout nature, infecting a variety of mammalian species with strict host specificity. In this respect, *P. jirovecii* (formerly *Pneumocystis carinii* f. sp. *hominis*) is restricted to humans (Stringer et al., 2002), causing severe pneumonia in patients having an impaired immune system (Figure 1(e) and 1(f)). CD4+ T-lymphocytes are essential for the control of *Pneumocystis* pneumonia (PCP) and a CD4+ T cell defect is a primary risk factor for development of PCP. A B-cell defect and lowered antibody production, however, also may predispose a patient to PCP. The patients at risk of PCP are mainly HIV-infected persons whose CD4+ cell count is <200 cells per μ l and whose viral replication is not controlled; other non-HIV immunocompromised hosts, such as those with hematological malignancies and solid tumors, solid organ, and bone marrow transplant recipients; and patients with collagenvascular disorders (Catherinot et al., 2010). The incidence of PCP has increased in non-HIV immunocompromised hosts while it has declined in HIV-infected individuals since HAART became available. No exosaprophytic form of *P. jirovecii* has been identified so far and the latent human sources may be represented by all infected or colonized individuals (Totet et al., 2003). Host-to-host transmission of *P. jirovecii* via the airborne route has been suspected in humans through the occurrence of clusters of PCP cases in hospitals (Choukri et al., 2010; Le Gal et al., 2012). *Pneumocystis* spp. is highly susceptible to trimethoprim-sulfamethoxazole (TMP-SMX), which is the first-line agent for the treatment of PCP in HIV and non HIV-infected patients. TMX-SMX is also the first-choice prophylaxis in HIV and non-HIV-infected hosts.

Endemic Fungal Infections

Infections Due to *Blastomyces dermatitidis*

Blastomyces dermatitidis is a dimorphic fungus endemic to the central and southeastern United States and also to some regions of Canada. Blastomycosis is acquired by inhalation of aerosolized conidia. Most infected individuals are asymptomatic or develop a self-limited respiratory illness. The dominant clinical manifestation of blastomycosis is a pneumonia that can be acute, subacute, or even chronic. The infection may disseminate to skin and bones or, less commonly, to the central nervous system and the meninges. The disease is more severe in patients with AIDS.

Infections Due to *Coccidioides* Species

Coccidioidomycosis is caused by the soil-dwelling fungi *Coccidioides immitis* and *Coccidioides posadasii*, which are localized to relatively arid regions of the Western hemisphere. Areas of highest endemism in North America are the San Joaquin Valley of California, the south-central region of Arizona, and northwestern Mexico. The number of reported cases of coccidioidomycosis has risen over the past decade: In Arizona and California, for instance, the incidence rates have increased by more than 90% from 2001 to 2006 (Hector et al., 2011). The vast majority of cases of coccidioidomycosis are acquired by inhalation. Approximately 60% of these infections are asymptomatic (Galgiani et al., 2005). Acute pulmonary coccidioidomycosis is not specific and the pulmonary syndrome mimics other community-acquired pneumonia syndromes or upper-respiratory-tract infections (Valdivia et al., 2006). It sometimes may be distinguished from other community-acquired pneumonia by the presence of hilar adenopathy, peripheral

blood eosinophilia, severe fatigue, night sweats, and erythema multiforme or erythema nodosum. In endemic regions, coccidioidomycosis might be responsible for nearly one-third of the patients presenting with lowerrespiratory-tract symptoms.

Infections Due to *Histoplasma capsulatum*

Histoplasma capsulatum is a dimorphic fungus reported in at least 60 countries worldwide, but it is endemic in the United States (especially in the Mississippi and Ohio river valleys) and in Central and South America. The natural habitat of this fungus is a soil with a high nitrogen content, such as those contaminated with bird or bat guano. Inhalation of aerosolized conidia and hyphal fragments from polluted soils is considered to be the main source of human contamination. The severity of illness after inhalation depends on both the intensity of exposure and the host immune status. Although the attack rate reaches 100% in certain areas, most cases remain asymptomatic and are detected only by skin tests (Kauffman, 2007). After exposure to a heavy inoculum, most individuals exhibit various symptoms from self-limited acute pulmonary histoplasmosis to disseminated histoplasmosis. Disseminated disease is much more common in young children and in immunocompromised adults, such as AIDS patients, organ transplant recipients, and patients receiving immunosuppressive chemotherapy. The mortality associated to disseminated histoplasmosis is high, up to 50%. The optimal treatment of histoplasmosis varies according to the patient's clinical syndrome (see Table 1) (Wheat et al., 2007).

Innate Immunity, Adaptive Immunity, and Fungal Infections

Fungal diseases are linked intimately to dysfunction of the immune system. Indeed, local or systemic, genetic, pathologic, or drug-induced alterations of the immune system will modify the equilibrium established between environmental or commensal fungi and the human body and favor fungal development and disease. Inversely, fungi can trigger an uncontrolled inflammatory response that has pathological consequences. In this respect, both innate and adaptive immunity play important roles in maintaining homeostasis with fungi (Romani, 2011). The knowledge that is being gained on these particular aspects of fungal infections certainly will contribute to their better management through the use of therapies aimed at modulating the immune system, the development of vaccines, or the genetic testing of patients to identify those at risk of developing some forms of fungal infections.

Innate immune mechanisms are used to sense and respond to fungal pathogens in a relatively unspecific manner. These mechanisms are effective at various sites of interaction with fungi. They include barriers, such as the skin and the mucosal surfaces of the respiratory, gastrointestinal, and genitourinary tracts (Romani, 2004). They also involve constitutive defense mechanisms, such as defensins, collectins, and the complement system. Fungi also harbor so-called pathogen-associated molecular patterns (PAMPs), whose recognition by host cell pattern recognition receptors (PRRs) triggers the activation of signaling cascades, the activation of the immune system, and fungal clearance. A majority of the known fungal PAMPs are constituents of the fungal cell wall that are shared by almost all fungi: chitin, a polymer of *N*-acetylglucosamine, and β -glucan, a polymer of D-glucose linked by β -(1,3) bonds and branched through β -(1,6) bonds, which together form the inner layer of the cell wall; mannose polymers (mannans), which decorate cell wall glycoproteins at *O*- and *N*-glycosylation sites and form the outer layer of the cell wall; α -glucan, a polymer of D-glucose linked by α -(1,4) bonds; and β -(1,2)-oligomannosides, which also are found on cell wall glycoproteins as well as cell wall lipopeptides (Munro and Richard, 2012). Although *N*-linked mannan, glucans, and chitin are recognized by C-type lectin receptors, *O*-linked mannan (as well as fungal RNA and DNA) are recognized by Toll-like receptors and β -(1,2)-oligomannosides are recognized by galectin-3 (Netea et al., 2008). Recognition of the PRRs results in activation of the nuclear factor κ B (NF- κ B) and the inflammasome. A consequence of this activation is the production of defensins, chemokines, and cytokines as well as phagocytosis and killing of fungal propagules (Romani, 2011).

Contribution of innate immunity components to antifungal defenses is highlighted by the increased susceptibility to fungal infections of patients receiving treatments that dampen innate immunity at different levels. Cancer chemotherapy, for instance, that affects the levels of neutrophils and alters the integrity of the intestinal epithelium is well known to trigger translocation of *C. albicans* from the gastrointestinal lumen to the bloodstream (Koh et al., 2008). Similarly, neutropenia is the main predisposing factor to invasive aspergillosis (Patterson et al., 2000; Segal, 2009). More specifically, mutations in genes that encode innate immunity components have been shown to predispose some individuals to fungal infection (Romani, 2011). Dectin-1 is a C-type lectin receptor that is responsible for the recognition of β -glucans (a major fungal cell wall component; see the next section) and subsequent activation of NF- κ B (Brown, 2006). Mutations in the Dectin-1 gene that result in the production of a shorter form of the protein and impair its ability to bind β -glucans and trigger the production of cytokines confer increased susceptibility to chronic mucocutaneous candidiasis, colonization of the gastrointestinal tract by *C. albicans*, and invasive aspergillosis (Ferwerda et al., 2009; Plantinga et al., 2009; Cunha et al., 2010). Similarly, mutations in Toll-like receptors that recognize fungal RNA and DNA and *O*-linked mannan predispose to different forms of aspergillosis and to *C. albicans* infections (Romani, 2011).

Recognition of fungal pathogens by monocytes, macrophages, and neutrophils as well as epithelial and endothelial cells mainly results in their phagocytosis and killing. In contrast, phagocytosis of fungal pathogens by dendritic cells (DCs) initiates T cell-mediated immune responses that can contribute to the clearance of fungal infection or promote fungal pathogenesis and cause tissue damage. Indeed, maturation of DCs triggers the differentiation of naïve T cells into effector T helper (T_H) cell subtypes that have different properties. Although T_H1 and T_H17 cells contribute to protective immunity against fungi, T_H2 cells favor fungal infection, allergic responses, and disease relapse. Notably, a predominant T_H1 response is associated with effective fungal

Table 1 Summary of recommendations for the treatment of invasive fungal infections

	Therapy		
Disease condition	Primary	Alternative ^a	Comments
Candidiasis (Pappas et al., 2010)			
Candidemia nonneutropenic adults	Fluconazole (800 mg loading dose day 1, then 400 or 6 mg kg ⁻¹ day ⁻¹) or caspofungin (70 mg loading dose day 1, then 50 mg day ⁻¹) or micafungin (100 mg day ⁻¹)		
Candidemia, clinically unstable and unknown species neutropenic patients	Lipid-based amphotericin B (3–5 mg kg ⁻¹ day ⁻¹) or caspofungin (70 mg loading dose day 1, then 50 mg day ⁻¹) or micafungin (100 mg day ⁻¹)	Fluconazole (800 mg loading dose day 1, then 400 or 6 mg kg ⁻¹ day ⁻¹) or voriconazole (6 mg kg ⁻¹ per 12 h × 2, then 3 mg kg ⁻¹ per 12 h) or high-dose fluconazole (800 mg day ⁻¹ or ~12 mg kg ⁻¹ day ⁻¹)	
Aspergillosis (Walsh et al., 2008)			
Invasive aspergillosis	Intravenous voriconazole (6 mg kg ⁻¹ every 12 h for 1 day, followed by 4 mg kg ⁻¹ every 12 h) until improvement, followed by oral voriconazole (200 mg every 12 h)	Intravenous liposomal amphotericin B (3–5 mg kg ⁻¹ day ⁻¹) or caspofungin (70 mg day 1 and 50 mg day ⁻¹) or micafungin (100–150 mg day ⁻¹) or posaconazole (200 mg four times daily, then 400 mg twice daily) or itraconazole (400–600 mg day ⁻¹) until resolution of disease	
Chronic necrotizing (semi-invasive) pulmonary aspergillosis	For mild to moderate disease, voriconazole (200 mg every 12 h) or itraconazole (400–600 mg day ⁻¹) until resolution or stabilization of all clinical and radiographic manifestations		
Mucormycosis (Limper et al., 2011)			
	Lipid formulations of amphotericin B (5 mg kg ⁻¹ day) or amphotericin B deoxycholate (0.7–1.0 mg kg ⁻¹ day ⁻¹)	Posaconazole (400 mg orally twice daily or 200 mg orally four times per day) (only some strains fully susceptible)	Exact dose and duration of treatment are not precise
Infections due to Trichosporon spp. (Limper et al., 2011)			
	Voriconazole	Posaconazole	
Infections due to Fusarium spp. (Limper et al., 2011)			
	Voriconazole or posaconazole or lipid formulation of amphotericin B		
Infections due to Scedosporium apiospermum (Limper et al., 2011)			
	Voriconazole (200 mg intravenously or orally twice daily) or posaconazole (200 mg four times daily)		
Cryptococcosis (Perfect et al., 2010)			
Cryptococcal meningoencephalitis HIV-infected individuals	Amphotericin B IV (0.7–1.0 mg kg ⁻¹ day ⁻¹) plus flucytosine (100 mg kg ⁻¹ day ⁻¹) for 2 weeks, followed by fluconazole (400 mg day ⁻¹ (6 mg kg ⁻¹ day ⁻¹) orally for 10 weeks) or liposomal AmB (3–4 mg kg ⁻¹ per day IV) plus flucytosine (100 mg kg ⁻¹ day ⁻¹) for 2 weeks, followed by fluconazole (400 mg day ⁻¹ (6 mg kg ⁻¹ day ⁻¹) orally for 10 weeks	Amphotericin B IV (0.7–1.0 mg kg ⁻¹ day ⁻¹) plus fluconazole (800 per day orally) for 2 weeks, followed by fluconazole (800 per day orally) 8 weeks	

(Continued)

Table 1 Continued

Disease condition	Therapy		Comments
	Primary	Alternative	
Pneumocystis jirovecii pneumonia (Limper et al., 2011)	Trimethoprim 15–20 mg kg ⁻¹ plus sulfamethoxazole 75–100 mg kg ⁻¹ daily for 3 weeks	Primaquine plus clindamycin or atovaquone	
Blastomycosis (Limper et al., 2011; Chapman et al., 2008)			
Mild to moderately ill patients with pulmonary and nonmeningeal disseminated blastomycosis	Itraconazole (200 mg twice daily for 24 weeks)		
Life-threatening severe blastomycosis	Liposomal amphotericin B (3–5 mg kg ⁻¹ day ⁻¹) or amphotericin B (0.7–1.0 mg kg ⁻¹ day ⁻¹) for 1–2 weeks, followed by itraconazole (200 mg twice daily for 6–12 months)		
Coccidioidomycosis (Limper et al., 2011)			
Diffuse pulmonary	Liposomal amphotericin B (3–5 mg kg ⁻¹ day ⁻¹) or amphotericin B (0.7–1.0 mg kg ⁻¹ day ⁻¹) until clinical improvement, followed by fluconazole (400 mg day ⁻¹) or itraconazole (400 mg day ⁻¹) for at least another year		
Disseminated, nonmeningeal (including bone disease)	Fluconazole (400 mg day ⁻¹) or itraconazole (400 mg day ⁻¹)		
Meningitis	Fluconazole (400–1,000 mg day ⁻¹) or itraconazole		
Histoplasmosis (Wheat et al., 2007)			
Mild pulmonary histoplasmosis	Itraconazole (200 mg twice daily for 12 weeks)		Treatment is usually unnecessary
Moderately to severely ill pulmonary histoplasmosis	Amphotericin B (0.7 mg kg ⁻¹ day ⁻¹) +/- corticosteroids for 1–2 weeks, then itraconazole (200 mg twice daily for 12 weeks)		
Progressive disseminated histoplasmosis	Lipid formulation amphotericin B (3–5 mg kg ⁻¹ day ⁻¹) for 1–2 weeks, followed by oral itraconazole (200 mg twice daily for 12 months)		

^aAlternative (salvage) therapy for patients refractory to or intolerant of primary antifungal therapy.

vaccination. The balance between these responses is a consequence of the levels of different cytokines that are produced by DCs as well as macrophages and epithelial cells upon their interaction with fungal pathogens and their combined PAMPs.

The contribution of T_H1 and T_H17 cells to protective immunity against fungi is highlighted by the increased susceptibility to fungal infections of patients with mutations in genes that encode components of these two arms of adaptive immunity. For instance, deficiency in the recognition of interferon- γ , a landmark of the T_H1 response, is associated with disseminated coccidioidomycosis (Vinh et al., 2009). On the other hand, the study of kindreds with cases of autosomal recessive or dominant chronic mucocutaneous candidiasis disease showed that diseased individuals had mutations in genes with roles in T_H17 cell responses such as those encoding the interleukin IL-17, its receptor or STAT1, a transcription factor that is involved in inhibiting T_H17 cell responses (Liu et al., 2011; Puel et al., 2011; van de Veerdonk et al., 2011). Inversely, mutations in genes related to T_H2 cell responses often are associated with fungus-associated allergic responses. An example of such mutations includes those resulting in increased IL4 production, a landmark of T_H2 cell responses, that favor recurrent vulvovaginal candidiasis and those in the IL4 receptor that favor allergic bronchopulmonary aspergillosis (Babula et al., 2005; Knutsen et al., 2006).

Fungal Pathogenesis from the Prism of Molecular Biology

Major progresses have been made over the recent years in our molecular understanding of the mechanisms involved in fungal pathogenesis. These progresses have been driven partly by the availability of genome sequences for a majority of the fungal pathogens of humans (Table 2). Indeed, transcriptomic and proteomic approaches to these organisms are now possible, allowing to identify genes and proteins whose expression levels are influenced under conditions relevant to the interaction with the host (*ex vivo* and animal models of infection) (Wilson et al., 2009; Kniemeyer et al., 2011). These progresses are also a consequence of the availability of methods for the manipulation of the genomes of fungal pathogens. These methods allow the construction of knockout mutants, overexpression mutants, and strains with gene fusions that can be used to assess transcriptional changes at the single-cell level in a host–pathogen interaction context (Noble and Johnson, 2007; Idnurm and Williamson, 2011). In some species in which the engineering of mutant strains through homologous recombination is tedious, alternative strategies to knock down gene expression have been developed taking advantage of RNA interference (Rappleye and Goldman, 2006). Currently, the combination of genome sequences and methods for genome engineering is driving the establishment of systematic collections of molecularly tagged knockout mutants and overexpression strains for the major fungal pathogens of humans in a way that allows the simultaneous monitoring of many strains in a single experiment (Roemer et al., 2003; Liu et al., 2008; Noble et al., 2010). These approaches already have provided insights in fungal pathogenesis and identified virulence factors or antifungal targets (Xu et al., 2007a; Liu et al., 2008; Noble et al., 2010).

As mentioned earlier, most fungal pathogens of humans are opportunistic rather than obligate pathogens and their ability to cause disease is a direct consequence of local or systemic alteration of the immune system. It ensues that these fungi have evolved to thrive in their natural environments rather than cause infection in humans, an aspect that should be taken into consideration when one discusses their virulence factors (Casadevall and Pirofski, 2007). For instance, soil fungi, such as *C. neoformans*, because of their frequent encounters with amoeboid predators, are likely to have evolved escape mechanisms that also allow them to counteract human phagocytes and contribute to their ability to persist in the host and cause disease (Steenbergen et al., 2001).

A number of human pathogenic fungi are able to transit between different morphological forms, a property that is linked intimately to their virulence potential. For instance, *C. albicans* can grow in yeast, pseudohyphal, and hyphal forms

(Sudbery et al., 2004). The switch between these forms is triggered by a variety of environmental cues, including temperature, serum, CO₂, pH, and surface contact. Several signaling pathways, notably those involving the secondary messenger cyclic adenosine monophosphate (cAMP) and the cAMP-dependent protein kinase, have been described that transduce these cues and allow *C. albicans* yeast cells to initiate a transcriptional program that leads to the expression of so-called hypha-specific genes, the reorganization of cell polarity and the inhibition of cytokinesis (Sudbery, 2011). Locking *C. albicans* in the yeast or hyphal forms generally is associated with virulence defects, and it has been shown that while yeast cells contribute to dissemination and surface colonization, hyphal cells contribute to invasion of host cells and tissues and to biofilm formation (Saville et al., 2003; Sudbery, 2011). *Candida albicans* hyphal cells are characterized by an arsenal of cell wall-anchored surface proteins (Munro and Richard, 2012). These proteins include cell wall remodeling enzymes, detoxifying enzymes, and adhesins that mediate the association to a variety of host and microbial proteins (Munro and Richard, 2012). It is notable that one of these proteins, Als3, can trigger clathrin-mediated endocytosis of the hyphal cells by host epithelial and endothelial cells (Phan et al., 2005; Moreno-Ruiz et al., 2009). Yet hyphal morphogenesis is not a prerequisite to *Candida* spp. pathogenesis as other species in this genus are unable to form hyphae. As mentioned, elevated temperatures favor the transition from the yeast to hyphal form in *C. albicans*. This contrasts with other fungal pathogens, such as *B. dermatitidis*, *C. immitis*, *H. capsulatum*, *P. brasiliensis*, *S. schenckii*, and *P. marneffei*, that grow in the hyphal form at low temperatures and in the yeast form at body temperatures (Gow et al., 2002). The ability of these fungi to switch to the yeast form appears crucial to pathogenesis and the expression of virulence genes (Nemecsek et al., 2006; Nguyen and Sil, 2008). Apart from the yeast-hypha dimorphism, several pathogenic fungi can undergo other forms of morphogenetic switches that favor virulence. For instance, *C. immitis* is forming endospore-forming spherules that contribute to its persistence in the host (Hung et al., 2007). *Candida neoformans* forms giant cells that result from endoreplication and consequently are polyploid. These giant cells may be part of the defense strategies that allow *C. neoformans* to evade the initial host immune response, establish lung infection, and thus prolong survival within the host (Zaragoza et al., 2010; Okagaki et al., 2010).

Key to the virulence of human pathogenic fungi are mechanisms that protect fungal cells from the host defense arsenal. For instance, fungal pathogens produce enzymes, such as catalases and superoxide dismutases, that contribute to the detoxification of reactive oxygen and nitrogen species produced by immune cells (Chauhan et al., 2006; Brown et al., 2007). Moreover, some species produce extracellular appendages that prevent them from being recognized by the host or from the toxicity of reactive oxygen species. Infecting *C. neoformans* cells harbor a capsule composed of glucuronoxylomannan and galactoxylomannan polysaccharides that is essential for virulence. Both polysaccharides have immunomodulatory activity and are likely, upon their release from the cells during infection, to circumvent the host immune response (Janbon and Doering, 2011). Similarly, *A. fumigatus* spores (conidia) harbor an external layer that is composed of hydrophobic proteins called hydrophobins. Conidia that lack the hydrophobin layer are recognized by the immune system, indicating a role of this layer in protecting *A. fumigatus* and possibly other airborne fungi against immune attack (Aimanianda et al., 2009). Environmental fungal pathogens also harbor melanin in their cell wall that protects them from phagocytosis and killing by reactive oxygen species (Jahn et al., 1997; Trofa et al., 2011). In this respect, in ascomycetes, melanin is the product of one of several gene clusters that are responsible for the production of secondary metabolites. Another example of such secondary metabolites is gliotoxin, which is produced by *A. fumigatus*. Gliotoxin has immune modulatory and apoptosis-promoting activities and yet does not appear to play a major role in *A. fumigatus* virulence (Scharf et al., 2012). *Aspergillus fumigatus* mutants that are defective for the expression of multiple secondary metabolism gene clusters have reduced virulence, suggesting that one or several additional secondary metabolites contribute to fungal pathogenesis (Bok et al., 2005; Perrin et al., 2007).

Fungal pathogens of humans are generally well equipped with nutrient acquisition systems: extracellular proteases and lipases for degradation of host proteins and lipids, oligopeptide transporters and amino acid permeases, and metal ion scavenging systems (Naglik et al., 2004; Schaller et al., 2005; Nierman et al., 2005; Butler et al., 2009; Almeida et al., 2009; Kronstad et al., 2011). Notably, comparative analyses of the genomes of pathogenic and nonpathogenic hemiascomycetous yeasts (the branch that includes *Candida* spp.) have revealed that gene families for these nutrient acquisition systems are expanded in the pathogenic species, consistent with a role in virulence (Butler et al., 2009). This is supported by the characterization of a variety of mutants although the contribution to virulence of these systems remains difficult to establish directly because of the large size of some gene families whose members are functionally redundant (Naglik et al., 2004). In particular, iron scavenging has been shown to be essential to virulence of several fungal pathogens of humans, such as *C. albicans*, *A. fumigatus*, *H. capsulatum*, and *C. neoformans* (Ramanan and Wang, 2000; Jung et al., 2006; Hwang et al., 2008; Schrettl et al., 2010). In this latter species, expression of many virulence genes is actually under the dependency of iron (Jung and Kronstad, 2011). This is one example of the ability of fungal pathogens to adapt to changing environments. Other examples include the regulation of the *C. albicans* yeast-to-hypha switch by a variety of cues, reflecting the ability of this species to adapt to different environments through the production of hyphae (see earlier) and the ability of several fungal species to adapt to hypoxic environments, an adaptation that is often essential for virulence (Willger et al., 2008; Askew et al., 2009; Ernst and Tielker, 2009).

Antifungal Strategies and Mechanisms of Resistance

Modes of Action, Activity Spectra, and Therapeutic Applications of Antifungal Agents

This section focuses on the antifungal strategies used for treatment of invasive mycoses. The overall number of antifungal agents currently available to treat the large spectrum of invasive fungal diseases occurring in humans remains limited to less than 15. These

antifungal agents belong to four different chemical classes: polyenes, pyrimidin analogues, azoles, and echinocandins. The recommendations for the treatment of invasive mycoses using these agents are summarized in Table 1, taking into account the disease manifestations for each infection and alternative options when they are available.

Polyenes

Polyene drugs (amphotericin B (AmB) deoxycholate and its lipid-associated formulations) act by binding to ergosterol, the major sterol component of fungal membranes, forming tiny holes or channels into the membrane. The formation of channels allows small molecules to diffuse across the membrane and leads to impaired cellular functions, resulting in cell death (Lemke et al., 2005). AmB is active against most yeast and filamentous and dimorphic fungi. AmB desoxycholate is administered intravenously, and is associated with a broad range of side effects and toxicity, above all nephrotoxicity. The lipid-associated formulations of AmB are less toxic than the parent compound and reduce renal toxicity (Dupont, 2002). Polyenes administered intravenously remain a major treatment option for severe fungal infections, particularly life-threatening illnesses, including aspergillosis, cryptococcosis, candidiasis, and severe cases of histoplasmosis, blastomycosis, coccidioidomycosis, and infections due to Mucorales.

Azoles

Like polyenes, azoles exert their action on the fungal membrane. Azole drugs target the ergosterol biosynthetic pathway by inhibiting a key enzyme, the lanosterol 14- α demethylase. This inhibition takes place through the binding of the free nitrogen atom of the azole ring to the iron atom of the heme group of the enzyme. The resulting accumulation and metabolism of 14- α methylated sterol species leads to the synthesis of toxic compounds, which are unable to successfully replace ergosterol (Vandeputte et al., 2012). Azoles are cyclic organic molecules that are divided into two groups depending on the number of nitrogen atoms in the azole ring: The imidazoles contain two nitrogen atoms and the triazoles contain three nitrogen atoms. Only the triazole agents are used for the treatment of invasive fungal infections. They include itraconazole, fluconazole, voriconazole, and posaconazole. The structural differences between triazole molecules dictate antifungal potency and spectrum, bioavailability, and drug interactions (Odds et al., 2003). Azoles are effective against dimorphic fungi. Itraconazole, voriconazole, and posaconazole have good activity against most yeast and filamentous fungi, in contrast to fluconazole whose activity is limited mostly to yeasts. Furthermore, itraconazole and fluconazole are ineffective against some emerging pathogens, such as *Scedosporium* spp. and *Fusarium* spp. Finally, azoles have no activity against Mucorales, with the exception of posaconazole, which is effective against some strains of Mucorales.

Echinocandins

The echinocandins belong to the most recent class of antifungal drugs. Echinocandins are synthetic derivatives of lipopeptides, which disrupt fungal cell wall through inhibition of the β -1,3-glucan synthase complex. This complex is responsible for β -1,3-glucan synthesis, a major component of the cell wall. Echinocandins are fungicidal against most *Candida* spp. and fungistatic against *Aspergillus* spp. These molecules have no activity against *C. neoformans* and Mucorales.

Antifungal Drug Resistance Mechanisms in Fungal Pathogens

As mentioned, several fungal pathogen species are intrinsically tolerant to a subset of antifungals. The mechanisms that underlie this tolerance are not understood, but they possibly involve the structure of the cell wall, the structure of the plasma membrane, or the constitutive activation of drug efflux mechanisms. Notably, antifungal tolerance contributes to a shift in the epidemiology of species, causing invasive fungal infections with antifungal-tolerant species progressively surpassing in frequency antifungal-sensitive species. For instance, *C. glabrata* is to some extent tolerant to azoles and the prevalence of invasive candidiasis due to this species currently is increasing whereas infections due to azolesensitive *C. albicans* are decreasing (Hachem et al., 2008). Acquisition of resistance to antifungals by fungal pathogens is another cause for the inefficacy of these drugs. Resistance can be achieved through mutations in genes encoding antifungal targets, thereby increasing the antifungal target levels in the cells or decreasing its affinity for antifungal molecules. This is the case in *C. albicans* in which mutations in the *ERG11* and *FKS1* genes have been shown to affect the affinity of the Erg11 lanosterol 14- α demethylase for azoles and the Fks1 β -1,3-glucan synthase catalytic subunit for echinocandins, respectively (Sanglard and Odds, 2002; Perlin, 2007). This is also the case in *A. fumigatus*, where a change in the number of tandem repeats in the promoter of the *cyp51A* gene encoding lanosterol 14- α demethylase confers azole resistance (Snelders et al., 2008). Alternatively, antifungal resistance can result from increased drug efflux. This is especially the case for azole drugs that are effluxed from fungal cells through two types of pumps, the ATP-binding cassette transporters – such as *C. albicans* Cdr1 and Cdr2 – and the major facilitators – such as *C. albicans* Mdr1 (Sanglard et al., 1997, 1995). Increased expression of the genes encoding these pumps results in decreased sensitivity to azoles. Interestingly, mutations in transcription factors that control the expression of genes involved in azole biosynthesis or drug efflux have been shown to contribute to the acquisition of azole resistance (Coste et al., 2006; Morschhauser et al., 2007; Dunkel et al., 2008) and it is notable that genome rearrangements, such as loss of heterozygosity, aneuploidies, and the formation of isochromosomes can enhance the effect of these mutations and, consequently, the level of azole resistance (Coste et al., 2007; Selmecki et al., 2006). In contrast, drug efflux does not appear to play a role in the sensitivity of fungal

cells to echinocandins, possibly because they appear to act on the extracellular side of the plasma membrane, where the β -1,3-glucan synthase resides, and resistance to polyenes rarely is seen, possibly because these drugs act by directly targeting the fungal membrane. Finally, because horizontal gene transfer is rare in fungi, antifungal drug resistance is probably of lesser concern than antibiotic resistance as seen in bacterial species. Yet, the limited number of antifungals available dictates that all efforts should be made to limit the emergence of resistance to these drugs.

Another source of antifungal tolerance results from the ability of numerous fungal pathogens to form so-called biofilms. Biofilms are three-dimensional microbial structures that develop on biotic or abiotic surfaces. Biofilm cells are embedded within an extracellular matrix and are highly tolerant to antimicrobial and immune insults (Donlan and Costerton, 2002). Fungal pathogens of the genus *Candida* form biofilms on catheters and prosthetic devices. *Candida* biofilms constitute an important pitfall in the management of disseminated *Candida* infections because of their intrinsic tolerance to almost all antifungals in clinical use (Kojic and Darouiche, 2004). *Candida* biofilms are especially resistant to azoles and amphotericin B but remain sensitive to the echinocandins (d'Enfert, 2006). Recently, major progress has been made in understanding the molecular mechanisms implicated in the building of *C. albicans* biofilms (Finkel and Mitchell, 2011). Additionally, major progress has been made in understanding the basis of antifungal tolerance of *C. albicans* biofilms. Notably, drug efflux does not appear to play a major role in antifungal tolerance of biofilms except at early phases of biofilm formation (Mukherjee et al., 2003). In contrast, entrapment of antifungals in the biofilm matrix made up of β -1,3-glucans seems central to the antifungal tolerance of biofilms because altering the matrix enzymatically or genetically dramatically enhances the antifungal susceptibility of *C. albicans* biofilms (Nett et al., 2007, 2010; Taff et al., 2012). Additionally, *C. albicans* biofilms contain persister cells that are highly tolerant to antifungals and may contribute to the overall antifungal tolerance of the biofilm (Lafleur et al., 2006).

Glossary

Bioprospectin The exploration of novel applications, processes or products in living systems.

Bioremediation Processes of exploiting living systems, usually microorganisms or their products, to clean the environment spoiled by contaminants, in a natural way.

Directed evolution A method by which DNA or proteins are made to evolve artificially in a short time using rounds of random mutagenesis followed by selection of variants with desired qualities.

DNA shuffling Also known as sexual polymerase chain reaction (PCR), a technique where similar but nonidentical DNA sequences are reassembled to obtain novel combinations of related sequences, to rapidly propagate beneficial mutations leading to directed evolution.

Genetic engineering Also referred to as genetic modification or gene splicing, this is a technique of altering the genes of an organism, to change the amount or type of proteins an organism produces.

Metabolic engineering A technology aimed at increasing the cellular production of a desired substance by modifying pathway flux using genetic means.

MPSS (massively parallel signature sequencing) A method to determine the expression of genes by measuring mRNA levels.

Pharming A process by which transgenic animals are made, using genetic engineering, and exploited to mass-produce pharmaceuticals and nutraceuticals.

SAGE (serial analysis of gene expression) A method to determine gene expression using conventional cloning and sequencing procedures.

Strain improvement A strategic approach of using mutagenesis and/or modern genetic manipulations to develop superior strains in terms of yields of desired products.

Therapeutic proteins Proteins produced by recombinant DNA for pharmaceutical use. transcriptional profiling A technique used to study the pattern of expression or regulation of genes, which indicates the function of genes.

Transgenic plants Also known as genetically modified (GM) crops, plants that have foreign genes inserted in them artificially to obtain plants with desired traits.

Whole-genome shuffling A technique combining multiparental crossing through DNA shuffling and recombination of entire genomes, which results in improved strains in a very short time.

Abbreviations

AIDS	Acquired immunodeficiency virus
BAC	Bacterial artificial chromosome
CHO	Chinese hamster ovary
DHAP	Dihydroxyacetone phosphate
EPO	Erythropoietin
FDA	Food and Drug Administration
GM	Genetically modified

[☆]*Change History:* October 2016. Preeti Vaishnav and Arnold L. Demain updated the title of the article, author affiliations, and following sections "Introduction," "Medical Biotechnology," "Antibiotics," "Therapeutic Proteins," "Microbial Cell Systems," "Higher Cell Systems," "Biopharmaceutical Markets," "Primary Metabolites," "Enzymes," "Bioplastics and Biopolymers," and "Biofuels."

This article is an update of P. Vaishnav, A.L. Demain, Industrial Biotechnology (Overview), *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 335–348.

GMP	5-Guanylic acid
GRAS	Generally recognized as safe
IMP	5-Inosinic acid
mAbs	Monoclonal antibodies
MPSS	Massively parallel signature sequencing
PCR	Polymerase chain reaction
PDO	1,3-propanediol
PHA	Polyhydroxy alkanoate
PHB	Polyhydroxybutyrate
PH3B	Poly(3-hydroxy-butyrates)
PHC	Polyhydroxycaproate
PHV	Polyhydroxyvalerate
PMP	Plant-made pharmaceutical
SAGE	Serial analysis of gene expression
TNF	Tumor necrosis factor
tPA	Tissue plasminogen activator
USDA	US Department of Agriculture
VEGF	Vascular endothelial growth factor
WGS	Whole-genome shuffling

Defining Statement

This overview of industrial biotechnology discusses the use of genetics in the production of medical pharmaceuticals and other products. It includes medical biotechnology (antibiotics, therapeutic proteins, protein production systems, and biopharmaceutical markets), primary metabolites, enzymes, biopolymers and bioplastics, biofuels, bioremediation, and agricultural biotechnology.

Introduction

Mankind has sought refuge in biotechnology for survival and betterment of human life for millennia. Selective breeding of plants and animals, discovering microbes and eventually harnessing them to produce cheese, bread, wine, vaccines and antibiotics, have all been initial strides taken toward the biotechnological journey. Today, we manipulate the genetic makeup of microbes to suit our requirements and use them as factories to produce hormones, antibiotics, enzymes, monoclonal antibodies, therapeutic proteins, plastics, silk, and biofuels, to name a few.

Many discoveries in genetics in the late 20th century laid a strong foundation in the field of biotechnology, for example, genetic engineering, and have empowered humankind to exert greater control over its life and well-being. An epic finding was that of Avery, MacLeod, and McCarty in 1944 that DNA, rather than proteins, was the carrier of genetic information. This was followed in 1953 by the elucidation by Franklin, Watson, and Crick of the structure of double-stranded DNA. In 1956, Rich and Davies discovered the RNA double helix and RNA hybridization. Discovery of restriction enzymes in 1962 by Arber broadened the prospects of genetic manipulation. Nathan and Smith showed that restriction enzymes cut DNA in a sequence specific manner. In 1967, DNA ligase was isolated, while in 1970, the first restriction enzyme, reverse transcriptase, which cuts DNA molecules at precise locations, was isolated by Temin, Baltimore, and Delbecco. These findings opened the way for a major breakthrough in biotechnology, that is, the discovery of recombinant DNA (rDNA) by Berg, Boyer, and Cohen in 1972–73. Recombinant DNA technology allowed the discovery of a series of synthetic proteins manufactured in microbial factories. The first one was the human protein somatostatin in 1977, followed by human insulin produced in *Escherichia coli* in 1978. In 1982, the first rDNA animal vaccine was approved for sale in Europe while in the same year, the first rDNA pharmaceutical (human insulin) was approved for sale in the United States and United Kingdom. Another outstanding discovery was that of phage display technology, first described by Smith in 1985. This technique is used in cloning a gene when an antibody against that gene product is available. Mullis discovered the polymerase chain reaction (PCR) in 1983, which is of incredible value in diagnostics and forensic medicine. In 1984, the entire human acquired immunodeficiency virus (AIDS) gene was cloned and sequenced, and Jeffreys introduced the technique of DNA fingerprinting for genetic identification. In 1986, the first genetically engineered human vaccine, Recombivax HB, was approved for the prevention of hepatitis B. In 1995, the bacterium *Haemophilus influenzae* had its entire genome sequenced. The first complete animal genome, that is of the worm *Caenorhabditis elegans* was sequenced in 1998. In that year, Thomson and Gearhart individually developed a technique for culturing embryonic human stem cells. In 2000, Golden Rice containing vitamin A was produced. Researchers sequenced the DNA of rice in 2002, the first crop to have its genome decoded. Marshall and Warren discovered the bacterium *Helicobacter pylori* and its role in gastritis and peptic ulcer, while Fire and Craig discovered RNA interference and gene silencing by small pieces of double-stranded RNA. Later, in 2003, the sequencing of the human genome was completed by Venter, Collins, and Lander; this threw much light on the field of medicine based on genetics.

Industrial biotechnology can be defined as the application of scientific and engineering principles to the processing of materials by microorganisms (bacteria, fungi, algae, protozoa, and viruses), plant cells and animal (insects and mammals) cells to create useful products or processes. The microorganisms used may be natural isolates, laboratory-selected mutants, or microbes that have been genetically altered using rDNA methods. Most antibiotics come from microbial fermentations involving a group of organisms called actinomycetes, which are filamentous bacteria. Yeasts are used in baking, in the production of alcohol for beverages and fuel (bioethanol), and heterologous proteins (especially mammalian proteins). This is due to the fact that knowledge of yeast genetics is more advanced than that of any other eukaryote. Microbial products include primary metabolites (amino acids, vitamins, purine nucleotides, organic acids, etc.) and secondary metabolites (antibiotics, antitumor agents, immunosuppressants, cholesterol-lowering agents, antiparasitic drugs, etc.), which microorganisms produce as part of their natural metabolism. The level of these metabolites produced by microbes is however very low, enough to satisfy their own requirements for life in the environment. Biotechnologists, utilizing mutational and genetic engineering techniques, modify the biosynthetic pathways leading to the desired product and develop strains that give rise to greatly magnified yields as compared to those of their parents. Molecular manipulation techniques such as recombinant DNA technology, hybridoma technology, and protein engineering provide us with tools to manipulate the genetic makeup of microbes, higher plants, and animals. Recombinant protein production can be improved using bacterial artificial chromosomes (BACs). Biotechnology has a key role to play in the healthcare, diagnostics, and agricultural industries along with others such as mining, petroleum, textile, food, and chemicals. Many medical products such as antibiotics, other low-molecular-weight pharmaceuticals, DNA vaccines, and human biologicals (e.g., insulin, growth hormone, and monoclonal antibodies) have been commercialized. Meanwhile, research continues to improve the production and decrease the costs using genetic engineering techniques. Diagnostic assays use monoclonal antibodies, DNA chips and marker enzymes, and so on, for the early detection of a myriad of diseases such as cancer, AIDS, hepatitis, and other viral diseases. Diagnostic kits including DNA chips, also known as DNA microarrays, have been commercialized using novel DNA sequencing methods such as MPSS (massively parallel signature sequencing) and SAGE (serial analysis of gene expression) to minimize production costs. The Human Genome Project revealed susceptibility genes for many diseases in individuals and allows humans to avoid the incidence of disease through preventive measures. The agricultural industry is largely benefitted by products of genetic engineering such as transgenic plants. These allow magnified yields, pest and weed resistance, and can be used by malnourished populations in developing countries. Genetically modified (GM) plants and animals can bring bewildering concepts to fruition. Already today, or on the near horizon, we have environmental-friendly plastics being made in *Arabidopsis thaliana* plants, pharmaceuticals being produced in corn, Golden Rice containing vitamin A, anti-allergic cats, and insect-resistant cotton. Developments in molecular biology have stretched beyond one's imagination, but commercialization of transgenic organisms does involve regulatory issues, and much caution has to be exercised to avoid mixing of genetically engineered organisms with wild-type organisms.

A novel approach of using synthetic biology is that of assembling biomolecular parts into systems that would carry out useful functions for human health, energy and the environment. Of importance has been the engineering of designer zinc-finger proteins that can bind to almost any DNA sequence.

Enzymes hold promising applications in industries such as foods, textiles, detergents, paper, and in sewage treatment. Enzymes and cells are of immense significance in biotransformations, also known as bioconversions. rDNA techniques help in designing enzymes that have improved stability, specificity, and activity. The commercial production and processing of a wide array of foodstuffs such as cheese, butter, chocolate, yoghurt, pickles, alcohols, food thickeners, flavoring agents, preservatives, artificial sweeteners, cured foods, and food supplements (vitamins and amino acids) require microbial activity. Some bacteria produce natural polymers and can be engineered to produce a range of thermostable polymers that can be used in all areas ranging from surgicals to packaging to plastics.

Isoprenoids, the largest group of plant chemicals, are produced naturally by plants and some microbes in very small amounts. Some like carotenoids, dolichols, ubiquinones, sterols, artemisinin and taxol can be produced by genetically-engineered microbes. They find application in pharmaceuticals, fragrances, solvents and recently, advanced biofuels.

Metallic nanoparticles have been used for catalysis, environmental remediation, gene therapy, drug delivery, imaging, as biomarkers, sensors, and energy. They can be synthesized by microbes. Bacteria can produce metal nanoparticles of different sizes and shapes. Mainly emphasized are silver, gold, palladium, copper, platinum, tellurium and titanium nanoparticles. The most important microbes for these purposes are species of *Pseudomonas*, *Enterobacter*, *Bacillus* and sulfate-reducing strains. Most of the synthesis is extracellular. Nanoparticles are important in fields such as physics, electronics, energy, chemistry, biology, pharmaceuticals, cosmetics, medicine, food industry, manufacturing, analytical chemistry, engineering, automotive, agriculture, and biological and environmental research. They can be used as catalysts, adsorbants, membranes, water disinfectants, and additives to increase catalytic activity and capability due to their high specific surface area and nanosize. Microbial synthesis of nanoparticles is new and of great interest, especially since chemical synthesis requires extreme conditions of pH and temperature, and the chemicals used may have environmental and human health impacts.

Medical Biotechnology

Genetic engineering using rDNA techniques is currently widely employed in the pharmaceutical industry and in human medicine. Drugs produced by biotechnological processes are used to treat invasive fungal infections, pulmonary embolisms, kidney transplant

rejection, infertility, growth hormone deficiency, diabetes, cancer, AIDS, and other serious disorders. In the future, drug therapy will become more personalized through the use of pharmacogenomics.

Recombinant immunotherapeutics are recombinant DNA products which have been useful in fighting cancer. The products generally kill the tumor and stimulate the immune cells to respond to the cancer cells. They include immunostimulants, vaccines, antibodies, immunotoxins, and fusion proteins. They were needed because conventional treatments (surgery, conventional chemotherapy, radiotherapy) were ineffective for half of the cancer patients. The new approach, called immunotherapy, is based on recombinant products and/or engineered cells that stimulate the immune system and reverse the tolerance provoked by cancer cells. Viruses are being studied as a means of killing tumors and training the immune system to combat cancer. There is one licensed oncolytic virotherapy which is used in China. Several late stage candidates, for example, Amgen's T-Vec and Sillajen's Vexa-Rec, are in late stage clinical trials.

Antibiotics

Molecular biology has a long history of contributions in the production of microbial pharmaceuticals, especially antibiotics. Antibiotics in 2004 had a market of \$26 billion of which the major groups were cephalosporins (\$7.3 billion), fluoroquinolones (\$6.2 billion), penicillins and macrolides (\$4.7 billion each), and others (\$3.1 billion). Most antibiotics are secondary metabolites, produced by bacteria (e.g., *Bacillus*, *Nocardia*, and *Streptomyces*) or fungi (*Aspergillus*, *Penicillium*, and *Cephalosporium*). Antibiotic production involves fermentation. Levels of antibiotics produced in nature are very low; hence, continuous efforts had to be made since the discovery of penicillin to commercialize these products. Classical strain improvement involves mutational techniques, wherein the producing culture is mutagenized using chemicals or irradiation or sometimes a combination of the two. Then, the mutagenized population is screened for antibiotic production and the best strain is chosen for further study, including nutritional optimization and further mutagenesis. This procedure of mutagenesis and screening ("brute force" strain improvement) is laborious and time consuming, but it works well.

The aims of mutagenesis programs include: (1) increasing titers, (2) allowing efficient assimilation of inexpensive, complex raw materials, (3) altering product ratios, (4) eliminating side products, (5) improving excretion of products, and (6) shortening of fermentation duration.

For 40 years, genetic recombination was ignored due to very low frequencies of recombination. However, protoplast fusion changed the scenario markedly. Protoplast fusion increased the frequency of recombination in *Streptomyces* from 10^{-6} to 10^{-1} . Selected mutant lines were recombined genetically by protoplast fusion to produce improved strains. Soon, transformation, conjugation, and recombinant DNA technology became routine in strain improvement along with mutation techniques. These technologies helped to (1) remove bottlenecks of rate-limiting reactions. For example, the expandase promotor of the penicillin biosynthetic pathway was replaced by the much more active ethanol dehydrogenase promoter. The new technology was also employed to (2) eliminate feedback regulation. This was seen in *Corynebacterium glutamicum* where the threonine dehydratase gene *ilvA* was replaced by a feedback resistant *ilvA* gene from *E. coli* to increase isoleucine production. The technology was also used to (3) manipulate control genes. In actinomycetes, extra copies of positive-control genes were inserted to improve production of actinorhodin, undecylprodigiosin, and spiromycin, whereas negative regulatory genes were deleted or inactivated in producers of methylenomycin, tetracenomycin, jadomycin, and duanorubicin. Another application was that of (4) perturbing central metabolism. For example, the first or second enzyme of the pentose phosphate pathway was deleted in *Streptomyces lividans* to increase actinorhodin production. (5) Blockage of competing pathways is another application, for example, by blocking tyrosine formation, an increase in phenylalanine titer was achieved. The technology was also used to (6) enhance product excretion; for example, *lysE* encoding the protein involved in lysine excretion was overexpressed to increase lysine production. (7) Another application is that of decreasing the wasteful conversion of the desired product to a less active or inactive compound. In this category, genes *dnrX*, *dnrH*, and/or *dnrU*, which are involved in the conversion of the desirable doxorubicin into other compounds, were disrupted, thus increasing doxorubicin titer by threefold. Finally, (8) increasing the dosage of biosynthetic genes often results in an increase in production. For example, increasing the dosage of early genes of the spinosyn pathway increased production by three- to four-fold.

Many newer genetic engineering techniques are used to increase production and thus decrease costs. These include transcriptional profiling, DNA shuffling, whole-genome shuffling (WGS), directed evolution, massive parallel signature sequencing, association analysis, genome-based strain reconstruction, and metabolic engineering. Transcriptional profiling was used for strain improvement of the industrial lovastatin producer, *Aspergillus terreus*. Dosage of seven biosynthetic and regulatory genes, *lovF*, *creA*, *fadA*, *ganA*, *gna1*, *gna3*, and *gpa1* was increased. Of the seven genes, *lovF* was found to be crucial for increasing lovastatin titer. The *lovF* promoter was fused with the bleomycin resistance gene *ble* and bleomycin-resistant mutants were isolated. Of these, one doubled lovastatin production.

DNA shuffling, a method of *in vitro* recombination was used to increase the titers of doramectin. The parent strain produced avermectins B1 and B2 in the ratio of 0.6:1, respectively; B1 being the favorable member of the pair. Random mutation of gene *aveC* was carried out by PCR, and a mutant with the more favorable ratio of 2.5:1 was produced. Finally, DNA shuffling was applied and the ratio was markedly increased to 15:1.

WGS combines the advantage of multiparental crossing allowed by DNA shuffling with recombination of the entire genome. This method was successfully used to improve tylosin production by *Streptomyces fradiae*. Classical strain improvement methods in industry took 20 years to enhance tylosin production sixfold. WGS gave similar results in just 1 year.

The above-described novel molecular manipulations of genetic engineering combined with the classical approach thus make strain improvement much faster. This strategy not only reduces the time but lowers the amount of labor needed for random mutational screening. When the entire biosynthetic pathway leading to the desired product is elucidated and all the regulatory aspects are known, only genetic engineering is required to increase production. However, if the pathway is not clear, a combination of mutagenesis, protoplast fusion, and genetic engineering can still be applied for strain improvement. Classical mutagenesis and screening used without modern molecular technology possess a major disadvantage of accumulating secondary mutations that are detrimental to performance.

In the postgenomic era, the technique of genome-based strain reconstruction is an attractive option. This technique has been used for the reconstruction of superior strains of L-lysine-producing *C. glutamicum*. By comparative genomic analysis, mutations in three genes were determined to be of significance in lysine production. They were a Val-59Mala mutation in the homoserine dehydrogenase gene (*hom*), a Thr-311Mile mutation in the aspartokinase gene (*lysC*), and a Pro-458Mser mutation in the pyruvate carboxylase gene (*pyc*). The *hom* and *lysC* mutations were introduced individually into the wild-type strain by allelic replacement. This resulted in accumulation of 8 and 55 g/L of L-lysine, respectively. Reconstitution of both mutations into the wild-type genome resulted in a sharp rise in production to 75 g/L of L-lysine due to a synergistic effect. Further introduction of the *pyc* mutation resulted in a further rise to 80 g/L of L-lysine within only 27 h. Thus, the titers as well as speed were increased, raising the overall efficiency of the fermentation process.

Directed evolution is a method to improve the properties of enzymes by evolving proteins with desirable properties not found in nature. For example, the enzyme deacetoxycephalosporin C synthase of *Streptomyces clavuligerus* was modified by directed evolution for enhancement of penicillin G expansion into phenylacetyl-7-aminodeacetoxycephalosporanic acid, an important intermediate in the industrial manufacture of cephalosporin antibiotics.

The biosynthetic pathways leading to formation of desired products can be modified and improved by carrying out metabolic engineering. The overall flux through a metabolic pathway depends on several steps, not on just a single rate-limiting reaction. When all the enzymes of a pathway are identified, a number of branch points are revealed which lead to other parts of metabolism. The flux can be increased by increasing the enzyme concentrations without perturbing the branch points, thus leaving other functions such as growth and cellular metabolism unchanged. For example, the overexpression of pyruvate carboxylase or aspartate kinase increased lysine production by *C. glutamicum* only marginally. But overexpression of both the genes increased lysine production by 250%.

Metabolic engineering has been applied to antibiotic production. The increases in metabolic flux were carried out by enhancing enzyme activity, manipulating regulatory genes, enhancing antibiotic resistance, and heterologous expression of novel genes. Techniques involving overall analysis of gene expression, that is, genomics, proteomics, and metabolomics have gone a long way in developing the strain to yield best results. Mutational techniques generate different desirable phenotypes. The mutants are then compared with the parent strain by functional genomic techniques such as (1) genomic DNA sequencing, (2) DNA sequencing of selected genes, (3) transcriptional profiling, (4) proteome analysis, (5) metabolic profiling, and (6) comparative flux analysis. In the application of inverse metabolic engineering, mapping of differences between strains with different degrees of a certain desired phenotype is done. Subsequent identification of factors conferring that phenotype is an essential part. Therefore, the tools of functional genomics have the potential to promote and expand inverse metabolic engineering. Gene expression analysis offers valuable insights toward increasing metabolite production. The commonly used methods are microarray technology, direct cDNA technology, SAGE, and MPSS. SAGE employs conventional cloning and sequencing procedures. MPSS is a method for counting innumerable mRNA molecules from a given sample. It uses a set of new technologies for cloning and sequencing a 16–20 base signature sequence from more than a million molecules simultaneously.

Considerable progress has been made in genomic sequencing of microbes. As of December 2006, there were 470 published genome sequences, and 991 bacterial, 631 eukaryotic, and 56 ongoing archaeal sequence projects. The presence of complete genome sequences has clearly allowed better targeting of genetic modifications. Fungal genomes that have been sequenced include *Saccharomyces cerevisiae*, *Schizosaccharomyces pombe*, *Aspergillus niger*, and *Neurospora crassa*. *S. cerevisiae* has 6294 genes, whereas actinomycetes have many more, for example, *Streptomyces coelicolor* with 7825 genes and *Streptomyces avermitilis* with 7574 genes. These numbers are about twice that possessed by *E. coli* (4289 genes) or *Bacillus subtilis* (4099 genes). *S. avermitilis* is the producer of avermectin, a commercial antihelminthic agent. Its genome sequencing revealed 30 gene clusters encoding pathways of secondary metabolism, including four clusters for melanin pigments, one for a carotenoid, one for a siderophore, three for type-1 polyketides, two for type-2 polyketides and non-ribosomal peptides, and four for terpenes. The total length of these clusters includes 271 genes, which is equal to 6.6% of the genome.

By 2002, over 22,000 bioactive compounds were described from microbes. These included 20,000 antibiotics produced mainly by the actinomycetes (45%). Fungi produced 35% and unicellular bacteria 17%, chiefly by species of *Pseudomonas* and *Bacillus*. Of the actinomycete antibiotics, about 80% are made by members of the genus *Streptomyces*. Genome mining of *Streptomyces ambifaciens* revealed production of new secondary metabolites over and above its known metabolites spiramycin and congocidine. They include kinamycins, stambomycins (macrolides) and antimycins, all showing antitumor activity. Other promising antibiotics are platensimycin and platensin produced by *Streptomyces platensis*.

In 1996, the anti-infective market reached \$23 billion and of these compounds, 160 were antibiotics. The market increased to \$44 billion by 2005. The antibiotic market reached \$30 billion in 2000 and \$31 billion in 2005. Despite these impressive figures, many large pharmaceutical companies have deserted the antibiotic field and transferred their interests to lifestyle drugs and drugs

that the public would use daily for the rest of their lives. Thus, the antibiotic discovery field is in the midst of a serious crisis at present. There is a growing need to develop or discover new antibiotics. Microorganisms are evolving rapidly to attain resistance to the prevailing antibiotics.

Antibiotic resistance poses serious threats to human and animal health. It is known that pathogens can be attacked by new or modified antibiotics, produced by microbial flora belonging to diverse sources such as soil and oceans. The bacteria follow Darwin's principle of survival of the fittest by being able to thrive despite adversity and to emerge stronger every time they survive an antibiotic dose. Frequent use of antibiotics and incomplete courses of treatment boost resistance in bacteria. Antibiotic resistance occurs by gene mutation and by transfer of resistance genes. Even unrelated bacteria can gain resistance from their neighbors through a phenomenon called horizontal gene transfer. This can occur by conjugation, transformation, or transfection. We know that resistant bacteria emerged just 4 years after drug companies began mass-producing penicillin in 1943. The first such bacterium was *Staphylococcus aureus*. Antibiotic resistance occurs mainly in "opportunistic pathogens" with moderate to low disease-causing potential. These organisms usually are naturally present in healthy humans. They only cause a disease when they infect parts of the body where they do not normally live, either through physical injury or surgery, or in patients with immature or defective immune systems. In some cases, the situation has become alarming, with the emergence of strains resistant to virtually every antibiotic. Some multiply-resistant strains of *S. aureus*, for example, cause serious hospital-acquired infections. One of the only compounds that can be used effectively against most of them is an older antibiotic, vancomycin. The development of multidrug-resistant strains poses a serious threat to human health. Until recently, new drugs have been developed in time to treat resistant bacteria. The scenario is now changing. Since 1998, as few as ten new antibiotics were approved by the Food and Drug Administration (FDA) and only two were truly novel. In 2002, around 89 new medicines emerged in the market, but none of these was an antibiotic. Particularly disturbing is the fact that there is no antibiotic class for which a bacterial resistance mechanism does not exist. In fact, it is alarming to know that DNA from soil samples when checked for antibiotic resistance showed positive results. However, recent discovery suggests a way toward tackling antibiotic resistance. The soil fungus *Aspergillus versicolor* produces aspergillomarasmine (AMA) which turns off a gene in bacteria that normally leads to antibiotic resistance. Together with a carbapenem antibiotic, AMA inactivates the gene New Delhi Metalloprotease 1 in *E. coli*, *Acinetobacter* and *Pseudomonas*. NDM-1 requires zinc and AMA removes zinc from the enzyme. The combination of AMA and the carbapenem has shown its effect in mice and in human cell culture.

In addition to antibiotic resistance development, other threats include the evolution of new pathogens (Ebola virus, HIV, etc.), toxicity of some known antibiotics and antitumor agents, and the existence of certain pathogens that have never been eliminated by antibiotics, for example, the *Pseudomonas aeruginosa* strain that infects patients suffering from cystic fibrosis.

New antibiotics can be discovered from sources such as microbial flora from oceans, other waters, and soil, collected from various areas around the world. There is an incredible diversity of microorganisms in our environment, but the problem lies in the difficulty of cultivating them. Microbial life in oceans is far more diverse than ever imagined, with more than 20,000 different kinds of bacteria living in 1 L of seawater. Researchers predict that the total biodiversity of bacteria in the oceans is probably greater than 5 million different kinds of microorganisms. One gram of soil contains about 10 billion microorganisms of more than 17,000 species. However, it is estimated that only 1% of bacteria and 5% of fungi have been cultivated in the laboratory. This problem is being actively studied by a number of groups. Some success is being achieved in growing uncultured microorganisms by a number of strategies: (1) using very low nutrient concentrations, (2) adding signaling molecules, (3) adding inhibitors of known microbes, (4) employment of long incubation periods, (5) use of growth conditions resembling natural environments, (6) protection from natural peroxides, (7) addition of humic acid, (8) employment of hypoxic or anoxic environments, (9) encapsulation of cells in gel microdroplets coupled with detection of microcolonies by flow cytometry, and (10) use of high CO₂ concentrations.

Another technique used to tap into biodiversity is that of metagenomics, also referred to as environmental or community genomics. Metagenomics proves to be of great use in genomic studies of uncultivable microbes. DNA is isolated from nature and cloned into *E. coli* by using bacterial artificial chromosomes (BACs). The size of DNA isolated from soil is usually up to 70 kb and that from water, up to 40 kb. BACs are capable of carrying inserts of up to 350 kb in size. Then, the *E. coli* clones are screened for biological activity. Of the secondary metabolites detected from metagenomic DNA, about half were known molecules but the other half were new compounds. Novel genes and gene products discovered through metagenomics include the first bacteriorhodopsin of bacterial origin; novel small molecules with antimicrobial activity; and new members of families of known proteins, such as an Na^b(Li^b)/H^b antiporter, RecA, DNA polymerase, and antibiotic resistance determinants.

The Epstein group at Northeastern University first used a diffusion chamber incubated in situ in which diffusion provided the microbes with their naturally occurring growth factors. Many more cultures were isolated from Nature by this method. They then devised an isolation chip (called the IChip) composed of several hundred miniature diffusion chambers. The IChip recovered many more isolates from Nature than even the diffusion chamber. Many of the species isolated have never been isolated before by standard techniques. Isolation from seawater was only 4% of inoculated cells which formed colonies in Petri dishes, as compared to 20% with the diffusion chamber and 34% with the IChip. The figures from soil were 7, 31 and 33%, respectively. By use of the IChip, 10,000 isolates were isolated from Nature. 25 potentially new antibiotics were found from these isolates. One of the microbes, isolated by IChip method, *Eleftheria terrae*, produced a new antibiotic. This organism is a new species of β -proteobacteria. By genome sequencing, it was found to be a member of a new genus related to Aquabacteria which are Gram-negative organisms, not known to produce antibiotics. The antibiotic was named teixobactin. It is an unusual depsipeptide containing enduracididine, methyl phenylalanine, and four D-amino acids. Its biosynthetic gene cluster consists of two large non-ribosomal peptide synthetase-coding genes. No mutants of *S. aureus* or *Mycobacterium tuberculosis* were resistant to teixobactin. It has excellent activity against Gram-positive pathogens including strains that are drug-resistant. Potency versus most Gram-positive species was below 1 μ g/mL. It is exceptionally active versus *Clostridium difficile* and *Bacillus anthracis*. Its killing activity of *S. aureus* was greater than that of

vancomycin. It was ineffective versus most Gram-negative bacteria except an *E. coli* strain with a defective outer membrane permeability barrier. No toxicity to mammalian cells was observed. It is an inhibitor of peptidoglycan synthesis with no effect on label incorporation into DNA. Its activity against *S. aureus* includes MRSA. It inhibits many other Gram-positive bacteria. Resistance to teixobactin could not be developed. It is active in the presence of serum. It is stable, has good microsomal stability and low toxicity. The antibiotic inhibits cell wall synthesis via binding to a highly conserved motif of lipid II (precursor of peptidoglycans) and lipid III (precursor of cell wall teichoic acid). Its target, lipid II, is a polyprenyl-coupled cell envelope precursor which is readily accessible on the outside of Gram-positive bacteria. The target is the pyrophosphate-sugar moiety of lipid II. The producer of teixobactin is a Gram-negative bacterium and its outer membrane prevents teixobactin from reentry into the producing organism. Teixobactin is distinct from glycopeptides, lantibiotics and defensins. It shows no cross-resistance with vancomycin which also is a lipid II binder. It showed no bad effects in toxicological in vitro investigation, i.e., hemolysis, cytotoxicity, hemolysis, etc.

New antibiotics can be created by combinatorial bio-synthesis, that is, by introducing genes encoding the antibiotic biosynthetic pathway into a foreign host, by changing the order of genes of an individual pathway in its native host, or by mixing genes from different pathways. Hybrid antibiotics were first produced by gene transfer between strains producing the isochromanquinone antibiotics actinorhodin, gramicin, and medermycin. Since then, many new hybrid antibiotics have been produced.

A protein central to both the development and transmission of antibiotic resistance is RecA, which is found in almost all bacteria. Researchers are trying to create a drug that would cause bacteria to become RecA-deficient, opening up a number of therapeutic possibilities. This research could create a new class of antibiotics or make bacteria more susceptible to existing antibiotics. An alternative approach would be to develop drugs that would impair the bacterium's ability to develop resistance.

Among the marine microbes, the genus *Salinispora*, belonging to the actinomycete family, has been discovered in five different oceanic systems around the world. These strains possess antibiotic and anticancer behaviors. Approximately 35% of discovered *Salinispora* strains demonstrate an ability to kill pathogenic bacteria and fungi. A compound produced by members of this genus is salinosporamide A, which affects tumor cells by preventing them from functioning. It prevents their proteasomes from destroying old proteins. Thus, these proteins pile up in the cell and hinder the cancer cell's performance. Marine organisms such as corals, sponges, fishes, and bryozoans are also promising candidates for discovering new drug molecules. In many of these cases, the secondary metabolite is produced by a microbe living synergistically with the higher life form.

Mycophenolic acid, produced by *Penicillium*, was never commercialized as an antibiotic but its 2-morpholino-ethylester was approved as a new immunosuppressant for kidney transplantation in 1995 and for heart transplants in 1998. Other immunosuppressants are cyclosporine, tacrolimus (FK506), and sirolimus (rapamycin). Some natural enzyme inhibitors such as the statins (compactin, lovastatin, and pravastatin) act as cholesterol-lowering agents. The statins, including the lovastatin-derivative Zocor and the synthetic Lipitor, have become the most economically important group of pharmaceuticals, exceeding sales of \$20 billion per year. Other bioactive natural molecules are also very important, such as antiparasitic agents (ivermectin), bioherbicides (bialaphos), plant growth regulators (gibberellins), biopesticides (polyoxins), bioinsecticides (spinosyns), and antitumor agents (doxorubicin, mitomycin, and bleomycin).

Therapeutic Proteins

The biopharmaceutical industry began with the establishment of the Cetus Corp. in Berkeley, California, in 1971. Within the next 2 years, Berg, Cohen, and Boyer discovered in vitro genetic recombination. In 1975, the first monoclonal antibodies were produced by Kolter and Milstein. In 1976, Genentech was founded. Yeast DNA was replicated and expressed for the first time in 1976, and in 1977, the first human gene was expressed in bacteria. Rutter and Goodman cloned the rat insulin gene, while Boyer's laboratory produced somatostatin in 1977. In 1978, Biogen was founded, Itakura produced recombinant human insulin, Baxter produced the first human growth hormone, and Fink inserted bacterial DNA into yeast chromosomes. In 1979, Baxter reported cloning the gene for human growth hormone. In 1981, scientists produced the first transgenic animals by transferring genes from other animals into mice. In 1986, the first genetically engineered human vaccine, Chiron's Recombivax HB, was approved for the prevention of hepatitis B. Genentech's tissue plasminogen activator (tPA), sold as Activase, was approved as a treatment for heart attacks in 1987. In 1997, the FDA approved Rituxan, the first antibody-based therapy for cancer. In 2003, the human genome was sequenced, stimulating researchers all over the world to develop new gene-based treatments for disease.

Proteins that are engineered in the laboratory for pharmaceutical use are known as therapeutic proteins. Most of biopharmaceuticals marketed to date are recombinant therapeutic protein drugs. These products have changed the life of humans as diabetics are now safe using human insulin instead of insulin of animal origin. Children with chronic granulomatous disease can lead a normal life due to interferon therapy. Patients undergoing cancer chemotherapy can recover quickly and suffer fewer infections by use of granulocyte colony-stimulating factors. These are only a few of the many benefits brought about by rDNA technologies.

The biotherapeutic proteins are being produced in microbial and mammalian cell systems. However, insect cells, transgenic plants, and transgenic animals are being developed as competitive processes.

Microbial Cell Systems

Recombinant proteins from the bacterium *E. coli* and the yeast *S. cerevisiae* make up about 40% of the therapeutic protein production market. Owing to scalability and well-characterized genetics, microbial host systems remain the best option for low-complexity and moderate-volume protein production at relatively low cost.

S. cerevisiae is a convenient host for producing pharmaceutical proteins especially of mammalian origin, due to many reasons: (1) it has attained GRAS (generally recognized as safe) status by the FDA; (2) it grows rapidly; (3) it secretes heterologous proteins extracellularly; and (4) knowledge of its genetics is greater than for any other eukaryote. Mammalian genes, such as those encoding human interferon, human epidermal growth factor, and human hemoglobin, have been cloned and expressed in *S. cerevisiae*. Also the production in this yeast of genes encoding surface antigens of the hepatitis virus resulted in the first safe hepatitis B vaccine. A major problem for *S. cerevisiae* is over-glycosylation. Other expression systems are the methanol-utilizing yeasts *Pichia pastoris* and *Hansenula polymorpha*. *P. pastoris* has been engineered to produce human-type glycosylation of recombinant proteins and will be very important in the future, especially for production of monoclonal antibodies.

With *E. coli*, the produced protein is not glycosylated, and if glycosylation is important, the bacterium cannot be used. Also, recovery can be challenging as the target protein is produced intracellularly. Robust recovery of recombinant proteins requires gentle lysis of cells after expression of the protein in the microbe's periplasm.

In addition to the above-mentioned microbes, other microbes have been used to make recombinant proteins. They include lactic acid bacteria, bacilli, corynebacteria, brevibacteria, streptomycetes, *Nocardia*, mycobacteria, halophilic bacteria, pseudomonads, caulobacteria and fungi.

Major problems with heterologous protein production in filamentous fungi are due to factors that influence production, that is, transcription, translation, secretion, and extracellular degradation. Different strategies have been developed to overcome these shortcomings, including the construction of protease-deficient strains, employment of strong fungal promoters, and increasing gene dosage. The introduction of a large number of gene copies, the use of efficient secretion signals, expression cassettes with strong fungal promoters, and fusions with a gene that encodes part of or an entire well-secreted protein have markedly improved production of recombinant proteins in fungi. Another problem lies in the postproduction recovery of proteins. Use of a secretory signal peptide fused to the N-terminus of the target protein can ensure efficient secretion of the protein. This eliminates the need for cell disruption and reduces interactions with host proteins. However, dilution of protein can be a shortcoming and proteins with complicated folding requirements and posttranslational modification steps cannot be improved with such a system.

Higher Cell Systems

Mammalian cells are used extensively for the production of complex human glycoproteins. It offers advantages such as proper protein folding assembly and posttranslational modifications. About 60% of therapeutic proteins, especially antibodies, are produced by mammalian cells. Cell lines generally used are Chinese hamster ovary (CHO), baby hamster kidney, human embryo kidney, and human retinal cells. Cell lines of human origin are now preferred as they allow production of target protein with human glycosylation patterns. The mammalian systems do suffer from high manufacturing costs however.

Production of recombinant proteins by the baculovirus-insect cell expression system has been used to produce tissue plasminogen activator, enzymes, viral proteins and parasitic proteins. Seven protein-based products have been commercialized. Four are veterinary vaccines, i.e., Porcelis Pesti from Merck, Bayovac from Bayer, Circo FLEX from Boehringer Ingelheim, and Porcilis PCV. The first two are for protection against swine fever virus and the last two are to protect against the porcine circovirus type 2. Three are for human parental use. They include Cervarix from GSK used to protect against cervical cancer caused by the human papilloma virus. Another is Provenge from Dendreon for treatment of prostate cancer. A third, FluBloc from Protein Sciences Corp., is used for immunization against disease caused by influenza virus subtypes A and B. Other vaccines are in development against many diseases.

Use of transgenic plants to make pharmaceuticals employs self-pollinating crops such as rice and barley for protein production. The major drawbacks include low levels of expression and environmental concern about contamination of nongenetically modified plants. Plant-made pharmaceuticals (PMPs) are produced in crops such as corn, tobacco, rice, and soy. The plant genes are manipulated to produce proteins with improved purity and activity. Transgenic plants offer benefits of being cost-effective, reduced chance of microbial contamination and increased production capacities. The first plant-made vaccine was approved by the US Department of Agriculture (USDA) in January 2006, validating the safety and efficacy of plant-made vaccines. Ventria Bioscience has developed an electrolyte solution using rice that is genetically altered to produce two breast milk proteins, lactoferrin and lysozyme. This plant-based electrolyte solution helped significantly in reducing the incidence of diarrhea and infections in children. Considerable efforts are being made to produce plant-based insulin using genetically altered safflower. This can meet the enormous supply needs and also reduce the capital costs and product costs substantially.

The first plant-based biopharmaceutical for humans to be approved by FDA was Eleyso (taliglucerase alfa) made by the Protalix company in Israel. It is used for the heritable Gaucher's disease. There are only two existing drugs for this disease but they are extremely expensive (up to \$300,000 per year). One of these is Cerezyme made by Genzyme and produced in modified hamster cells. Problems with Cerezyme manufacture have limited its supply. Eleyso is made in carrot cells. Taliglucerase alfa replaces the malfunctioning enzyme which causes Gaucher's disease. The malfunction leads to fat accumulation resulting in bone deterioration and anemia.

Attempts are being made to develop transgenic farm animals that produce pharmaceuticals and nutraceuticals. This is also referred to as pharming. Transgenic animals can be used to produce therapeutic proteins, especially for those that are complex, difficult to express, and require mass production. Among GM animals, goats are preferred because of their well-developed transgenic technology and high yield per liter of milk. More than 85 proteins including human blood proteins, for example,

antithrombin, 1A trypsin, 1 antitrypsin, and fusion antibodies have been produced in goats. Transgenic animals have a major benefit of low-cost production once they are developed, but disadvantages exist such as difficulty and the length of time required in establishing such engineered animals.

Biopharmaceutical Markets

The market for therapeutic proteins reached \$47.4 billion in 2006. Today, therapeutic proteins are used to relieve patients suffering from many conditions, namely cancer (monoclonal antibodies, interferon), heart attacks, strokes, cystic fibrosis, Gaucher's disease (enzymes, blood factors), diabetes (insulin), anemia (erythropoietin (EPO)), and hemophilia (blood clotting factors). The leading classes of therapeutic proteins in 2003 were EPO, monoclonal antibodies, and interferons.

Biopharmaceuticals made by mammalian cell cultures, especially monoclonal antibodies, continue to grow as an important class of pharmaceutical products. In 2012, biopharmaceuticals reached sales of \$130 billion which was 13% of the total market for pharmaceuticals. 34 were "blockbusters" (i.e., sales over \$1 billion) and more than 60% were produced by mammalian cell cultures. Of the ten best-selling pharmaceuticals, five are biopharmaceuticals and four of the five are monoclonal antibodies (Humira, Enbrel, Remicade and Rituxan).

The market for EPO grew from \$200 million to \$2 billion in a span of 5 years from 1990 to 1995. It grew further to \$3.5 billion by 2000 and to \$11.8 billion by 2004. Sales of other polypeptides such as human insulin (Novolin and Humulin) reached \$12 billion, while that of interferon-(Intron A) amounted to \$3.8 billion, the white blood cell stimulant Neupogen (filgrastim) \$3 billion, interferon- α (Avonex for multiple sclerosis) \$2.2 billion, human growth hormone \$1.8 billion, recombinant hepatitis B vaccine and somatropin (Humatrope and Neutropin) \$0.9 billion, and cerezyme \$0.7 billion.

The fastest growing therapeutic protein class is that of monoclonal antibodies (mAbs), with a 2012 market of \$18 billion. Monoclonal antibodies have diagnostic applications (determination of ovulation, pregnancy, and identification of infectious agents) and therapeutic uses (specific drug delivery in cancer therapy, destruction of platelet-catalyzed blood clots in heart disease therapy). They act as magic bullets by binding target proteins or by blocking the binding of target proteins. They bring a drug or a radioisotope to a designated target. ReoPro was the first successful therapeutic mAb approved in 1994 and reached a market of \$384 million by 2002. By inhibiting platelet aggregation, it successfully prevented complications of angioplasty such as heart attack and death. Rituxan, used for non-Hodgkin's lymphoma, achieved sales of \$5.9 billion. Enbrel, binding tumor necrosis factor (TNF), a protein involved in inflammation, and Remicade and Humira used for rheumatoid arthritis reached \$1.5 billion in sales in 2002. Avastin is the first antiangiogenesis drug acting against vascular endothelial growth factor (VEGF), an angiogenic factor. Today, more than 20 mAbs are on the market and more than 100 are under clinical trials for allergy, asthma, autoimmune diseases, cancer, cardiovascular diseases, transplantation, and viral infection.

In 2012, the biopharmaceutical market was constituted by over 300 proteins and monoclonal antibodies with sales of over \$100 billion. Hormones sold for over \$11 billion and growth factors over \$10 billion. Biopharmaceuticals have the fastest growth rate on the market, i.e., 19%. About 40% are produced by mammalian cell cultures, mainly CHO cells which have glycosylation patterns similar to that of human proteins. *E. coli* produces another 30% of products and *S. cerevisiae* produces 20%.

In 2012, twelve biopharmaceuticals were approved in the United States and/or Europe. This compared to ten in 2008, 20 in 2009, 13 in 2010, and six in 2011. Of the twelve were three enzymes, three antibodies, two fusion proteins, a gene therapy product, a regulatory peptide, a blood product, and a colony stimulating factor. The systems for production were mammalian cells, mainly CHO, for five of the products, and three in *E. coli*, including recombinant human glucocerebrosidase, used as replacement therapy for Gaucher disease. A new process was developed to make eicosapentaenoic acid (EPA), which is a long chain polyunsaturated fatty acid (PUFA), one in *S. cerevisiae*, one in *P. pastoris*, and one in an engineered plant. The plant-based product was Eleyso (taliglucerase alfa). The process uses an engineered strain of *Yarrowia lipolytica*. The oil produced has much higher levels of EPA than natural oils. EPA is important for the anti-inflammatory activity of fish oils, thus contributing to cardiovascular and joint health. The product is being commercialized by DSM. The yeast was engineered by transformation with 21 heterologous genes encoding five different activities.

Production of biopharmaceuticals by *S. cerevisiae* includes insulin and insulin analogs. Other products are human serum albumin, hepatitis vaccines, and virus-like particles used for vaccination against human papilloma virus. Other areas of current active research in the field of therapeutic biotechnology include research on vaults, that is, cell organelles made of ribonucleoproteins. These naturally occurring nanocapsules could provide a whole new class of delivery vehicles for therapeutic drugs and DNA. Indeed, vaults could be used for a wide range of applications in nanobiotechnology such as DNA delivery to correct mutations, enzyme delivery to replace or insert missing enzymes, and targeted drug delivery. Recently, genes that have a role in longevity and youthfulness have gained a lot of attention. Sirtuins are a family of genes that may be the master regulators of survival mechanisms at the time of stress, and understanding how they produce their health- and longevity-enhancing effects could lead to disease treatments and eventually longer disease-free human life spans. The biotechnology industry has now taken major strides by encompassing ribozymes, antisense molecules, monoclonal antibodies, gene and cell therapy, genomics, proteomics, metabolomics, pharmacogenomics, drug delivery, nanobiotechnology, bioinformatics, combinatorial chemistry, and developmental biology. These developments in genetic engineering have made tremendous impacts on almost all aspects of life.

Viruses are being studied as a means of killing tumors and training the immune system to combat cancer. There is one licensed oncolytic virotherapy which is used in China. Several late stage candidates, for example, Amgen's T-Vec and Sillajen's Vexa-Rec, are in late stage clinical trials.

Primary Metabolites

New processes for production of amino acids, flavor nucleotides, vitamins, and organic acids have been developed by recombinant DNA technology. *E. coli* strains were constructed with plasmids bearing amino acid biosynthetic operons. Plasmid transformation was accomplished in *Corynebacterium*, *Brevibacterium*, and *Serratia* and, as a result, recombinant DNA technology has been routinely used to improve such commercial amino acid-producing strains. New technologies which have proven to be very useful for increasing production of primary metabolites include genome-based strain reconstruction, metabolic engineering, and whole genome shuffling. Processes improved by genetic engineering include those for L-lysine, L-threonine, L-valine, L-tryptophan, L-proline, L-leucine, L-isoleucine, 5-guanylic acid (GMP), 5-inosinic acid (IMP), riboflavin, biotin, ascorbic acid, citric acid, gluconic acid, acetic acid, D- and L-lactic acid, and succinic acid, among many others.

The worldwide production of amino acids amounts to 4.5 million tons per year. L-tryptophan is produced at 14,000 tons per year, and L-phenylalanine at 30,000 tons per year.

High levels of primary metabolite production are as follows (in g/L): glutamic acid: 146; pyruvic acid: 135; citric acid: 250; isopropanol: 143; isobutanol: 111; 1,3-propanediol: 135; L-tyrosine: 50; isoprene: 60; farnesine: 100; poly(3-hydroxybutyrate): 141; polyhydroxyalkanoate: 100; 3-hydroxypropionic acid: 42; muconic acid: 36; 3-methyl-1-butanol: 9.5; amorphadiene: 40; artemisinic acid: 25; lipids: 25; isobutyl acetate: 17; parahydroxy styrene: 17; hydroxybutyrate 9.

Amino acids are a leading category of primary metabolites produced commercially. Metabolic engineering has increased the microbial production of L-valine. Engineered *E. coli* can produce 60 g/L with a productivity of 2 g/L h and a yield of 0.34 moles of valine per mole of glucose. Engineered *C. glutamicum* can make 172 g/L of L-valine with a yield of 0.63 moles per mole of glucose. L-valine is used in human and animal nutrition, manufacture of pharmaceuticals, as a moisturizing compound in cosmetics, and for chemical synthesis of antibiotics, antivirals, and herbicides.

Activities of L-arginine include stimulation of secretion of growth hormone, prolactin, insulin and glucagon, promotion of muscle mass, and enhancement of wound healing. High production of L-arginine has been achieved with metabolically-engineered *C. glutamicum* at 92.5 g/L. The arginine derivative L-ornithine can be produced at 51.5 g/L by another genetically-engineered strain of *C. glutamicum*.

Putrescine production has reached 24.5 g/L with metabolically-engineered *E. coli*. Fermentative production of glucosamine (GlcN) and N-acetylglucosamine (GlcNAc) has been accomplished. GlcN is used for relief of osteoarthritis. Current global sales amount to \$2 billion. Recombinant *E. coli* can produce 110 g/L of GlcNAc. GABA (gamma amino butyric acid), used in pharmaceuticals and functional foods, is produced by genetically engineered *C. glutamicum* at a level of 29.5g/L.

Carboxylic acids are made mainly by catalysis from petroleum-based precursors but interest in microbial production is increasing. Annual production of these organic acids is as follows (kt/year): acetic acid: 10,000; glycolic acid: 40; 3-hydroxypropionic acid: 3600; acrylic acid: 4200; lactic acid: 450; fumaric acid: 200; malic acid: 60; succinic acid 37; itaconic acid 80; citric acid 1600; adipic acid 3000; gluconic acid 87; glucaric acid: 42. Acetic and lactic acids are used as food preservatives.

Polyunsaturated fatty acids (PUFAs) are used as nutraceuticals and include (a) gamma linoleic acid (GLA; 18:3 omega-6) from *Mucor circinelloides*, (b) docosahexaenoic acid (DHA; 22:6 omega-3) from *Cryptocodinium cohnii* and *Schizochytrium/Thraustochytrium spp*, (c) arachidonic acid (ARA; 20:4 omega-6) from *Mortierella alpine*, and (d) eicopentaenoic acid (EPA) from genetically-modified *Y. lipolytica*. They represent a multi-billion dollar industry, mainly ARA and DHA for infant formulas. Microbial fermentation can be used for their production. Microbial oils can be made by 30–40 species of yeast; also by molds and algae. They are called oleaginous microbes. Fungi can accumulate 70% of their biomass as oils. DHA is produced at 2000 tonnes per year and has a market of \$317 million. It is produced by algae including a group of *Schizochytrium*, *Aurantiochytrium* and *Ulbongichytrium* species. EPA-producing microbes are microalgae. *Nitzschia laevis* makes 1 g/L of EPA.

Carotenoids are terpenoids, composed of hydrocarbons (beta-carotene and lycopene) or oxygenated derivatives known as xanthophylls, for example, lutein, zeaxanthin, astaxanthin. The carotenoid market in 2010 was \$1.2 billion. Astaxanthin is very efficient as a scavenger of reactive oxygen species. Beta-carotene is more potent against reactive nitrogen species. *E. coli* can produce 220 mg/L of lycopene. A recombinant strain of *Pseudomonas putida* can produce 239 mg/L of zeaxanthin. The market for beta-carotene was \$223 million in 2010 and that for astaxanthin reached \$225 million. Zeaxanthin is produced by microalgae and marine bacteria. A high level of 512 mg/L is produced by the marine bacterium *Flavobacterium multivorum*. It can also be made by metabolically-engineered *E. coli* at 1.6 mg/g DCW.

Microbes produce vitamin B₁₂ at high levels, for example, the aerobe *Pseudomonas denitrificans* at 214 mg/L and the anaerobe *Propionibacterium shermanii* at 300 mg/L. Chemical synthesis requires more than 60 steps.

Enzymes

In all living systems, most of the chemical reactions are mediated by enzymes – the biocatalysts. Enzymes are extensively used in the food industry (production of cheese and clarification of apple juice), textile industry (development of more efficient laundry detergents), paper industry, and in treatment of sewage. Living cells make enzymes and the strains are improved for better yield, and improved characteristics such as specificity, stability, and performance in industrial processes. Although the concentration of

individual enzymes in cells is typically less than 1%, this can be increased by use of gene amplification techniques. The enzyme market reached \$1.6 billion in 1998 for the following application areas: food 45%, detergents 34%, textiles 11%, leather 3%, and pulp and paper 1.2%. This does not include diagnostic and therapeutic enzymes. The market for these non-pharmaceutical proteins reached \$5 billion in 2015.

Recombinant fungi are one of the main sources of enzymes for industrial applications. More than 60% of the enzymes used in the detergent, food, and starch processing industry are recombinant proteins. Amylases, isolated mainly from *Bacillus licheniformis*, are used in sizing starch by the textile industry. Pectolytic enzymes are utilized for preparation of textiles such as hemp and flax. Catalases are used for removal of hydrogen peroxide prior to dyeing during textile processing. A number of enzymes are used for stain removal and allow mild washing conditions, thereby protecting the fabrics. The detergent industry employs cellulases for biopolishing of fabrics, and proteases isolated from *B. licheniformis* and *Bacillus amyloliquefaciens* for wools. Microbial lipases have a huge potential in areas such as food technology, and biomedical sciences, since they are stable in organic solvents, possess broad substrate specificity, do not require cofactors, and exhibit high enantioselectivity. In the food industry, lipases are commonly used in the production of fruit juices, baked foods, to form desirable flavors in cheeses, and interesterification of fats and oils to produce modified acylglycerols. There are three fungal recombinant lipases currently used in the food industry. They are from *Rhizomucor miehei*, *Thermomyces lanuginosus*, and *Fusarium oxysporum*, and are produced in *Aspergillus oryzae*. Lipases are employed in leather processing where they are combined with proteases, peroxidases, and oxidases. To be effective in detergents, lipases need to remain functional under harsh conditions such as the presence of surfactants and oxidants, temperatures above 45°C, pH values of about 10, and should be alkalophilic. In 1994, Novo Nordisk introduced lipolase, the first commercial recombinant lipase for use in a detergent by cloning the *Humicola lanuginosa* lipase gene into the *A. oryzae* genome.

Enzymes have great use in biotransformations. Either intact cells, an extract from such cells, or an isolated enzyme may be used as the catalytic system for a specific reaction. Biotransformation is highly cost-effective as compared with chemical transformation. Enzymes are employed in biotransformations for production of organic acids, steroid hormones, and antibiotics, in precious metal recovery (*Chlorella vulgaris*) and bioleaching of metals (*Thiobacillus ferrooxidans*), providing recovery of up to 70% of copper from low-grade ores.

Recombinant DNA has widened the scope of enzyme production and its applications. Plant and animal enzymes can be produced by microbial fermentations. It also enables production of enzymes from microorganisms difficult to grow or handle genetically by fermentation. Enzyme productivity can be enhanced by introducing multiple gene copies, introducing strong promoters, or using efficient signal sequences. Enzymes from pathogens or toxin producers can be produced in safe hosts. Designer enzymes with excellent selectivity and turnover rates can be created using directed evolution and rational design. Molecular modeling facilitates a detailed understanding of the catalytic mechanism and determinants of an enzyme–substrate reaction, which further helps in rational designing of enzymes.

Genetic engineering is used to produce microorganisms with altered enzymes or enzyme activities to achieve better yields of desired precursors, intermediates or products, such as polyketides, nonribosomal peptides, steroids, vitamins, and unnatural amino acids in an efficient manner. The use of directed evolution has rapidly emerged as the method of choice for the development and selection of mutated enzymes with improved properties. A variety of such methods have been used to alter the activity, stability, and availability of an array of enzymes. Currently, research is focused on bioprospecting for enzymes that fit specific applications. A majority of enzymes isolated from natural sources cannot meet the stringent demands of industrial and biotechnological applications, posing an exciting challenge for scientists. Modern biotechnological techniques enable modification of enzyme structure and function to exacting specifications. Directed evolution has allowed the generation of enzymes with greatly improved characteristics, and in some examples, with completely novel substrate specificities. It can help to design enzymes according to their potential applications. About 640 enzymes were structurally characterized by crystallization by 2000 and 3000 enzymes were identified by 2003.

Many natural enzymes have low stability, lack specificity and have low catalytic efficiency. This is being corrected by enzyme engineering techniques, i.e., chemical modification, phage display, rational design and directed evolution. The most commonly used are rational design and enzyme evolution.

Directed evolution has been successful in tailoring enzymes to improve their applications by changing substrate selectivity and evolving function de novo. It involves iterative mutagenesis followed by screening or selection. It can improve enzyme properties and functions even without much knowledge of enzyme structure. Important applications of directed evolution include modulating properties of enzymes acting on starch and alpha-glucans, and in organic synthesis, such as ketoreductases, monooxygenases, lipases and aldolases for improvement in activity, stability and enantioselectivity. Enzymes modified include those involved in biosynthesis, modification and degradation of carbohydrates, for example, ADP-glucose pyro-phosphorylase, amylosucrase, cytochrome P450, aldolase, sugar kinase, cellulase, amylase, xylanase and glucose dehydrogenase. Other improved enzymes are those involved in pharmaceutical production such as (R)-transaminase, keto-reductases, glucose dehydrogenase and haloalkane dehydrogenases used to make pharmaceutical ingredients. Success stories include (a) alcohol dehydrogenase with a ten-fold improvement over the wild-type enzyme at low temperature, and (b) keto-reductase/glucose dehydrogenase activity in which 160 g/L of substrate was converted with over 99.9% ee and 95% isolated yield in 8 h. Organisms used as enzyme producers include *E. coli*, *B. subtilis*, *Bacillus megaterium*, *Bacillus brevis*, *Lactobacillus lactis*, *P. pastoris*, *S. cerevisiae*, *H. polymorpha*, *Kluyveromyces lactis*, *S. pombe*, *Y. lipolytica*, *Aryula adenivorans*, *Candida boidini*, *A. oryzae*, *A. niger*, *Trichoderma reesei*, *Trichoderma atroviride*, *Penicillium sordida*, *Penicillium griseoroseum*, *Penicillium purpurogenum* and *Rhizopus oryzae*. Large proteins (>100 kD) are usually expressed in eukaryotes while small proteins (<30 kD) are expressed in prokaryotes.

Bioplastics and Biopolymers

Plastics are traditionally manufactured using fossil fuels. These petrochemical plastics have high durability but can-not be degraded easily, and eventually increase the bulk in landfills. This, along with the escalating costs of fossil fuels, prompt the plastic industry to adapt nature's resources to replace petroleum-based synthetics with bioplastics. Materials produced by living species, such as bacterial polyesters, lactic acid, and triglycerides are being polymerized to produce bioplastics. The kind of microbial plastic produced depends on the polymer produced by bacteria, which, in turn, is related to the carbon source used. Acetate and butyrate yield polyhydroxybutyrate (PHB), caproate yields polyhydroxycaproate (PHC), and valerate yields polyhydroxyvalerate (PHV).

Polyhydroxy alkanates (PHAs) are naturally produced by many bacteria as energy reserves. These compounds have properties similar to synthetic thermoplastics and elastomers but are completely and rapidly degraded by bacteria in soil or water. PHAs were produced at 350,000 metric tons in 2006. Most biopolymers are produced by chemical synthesis from non-renewable resources or by extraction from plants, animals, or algal biomass. Microbial production of the prebiotic poly-hydroxybutyrate (PHB) costs 5–10 times more than for synthesis of petrochemical polymers. The gamma-polyglutamic acid polymer made by *Bacillus* spp has a titer of 101 g/L and that of xanthan gum is 62 g/L. Total market for biopolymers was \$600 million in 2011.

The most abundant PHA is poly(3-hydroxy-butyrate) (PH3B), which bacteria synthesize as a part of their natural metabolism, from acetyl-CoA. Growing on glucose, the bacterium *Ralstonia eutropha* can accumulate up to 85% of its dry weight as PHB, which makes this micro-organism a miniature bioplastic factory. However, a major limitation in the commercialization of such bacterial plastics is their cost, being 5–10 times more than that for petroleum-based plastics. Much effort has therefore gone into reducing production costs with the aid of modern genetics, by developing superior bacterial strains in terms of polymer production. Recently, a novel alternative of generating transgenic plants that synthesize PHAs has emerged, which seems to be an economical and environmentally friendly approach to mass-produce bioplastics. The transgenic *A. thaliana* plant constructed had *R. eutropha* genes encoding two enzymes involved in the conversion of acetyl-CoA to PHB. Biocompatibility and biodegradability make PHB fibers ideally suited for surgical use; sutures made from PHB are only slowly degraded by the body's enzymes.

A new environmental-friendly and economical bioplastic is polytrimethylene terephthalate (3GT polyester; 3G τ ; Sorono), made by reacting terephthalic acid with 1,3-propanediol (PDO; trimethylene glycol; 3G). Scientists at Genencor International and DuPont jointly worked to develop a genetically engineered *E. coli* culture, by introducing eight new genes to convert dihydroxyacetone phosphate (DHAP) into PDO. These included yeast genes converting dihydroxyacetone into glycerol and *Klebsiella pneumoniae* genes converting glycerol into PDO. This recombinant *E. coli* grows on glucose and produces PDO at 135 g/L, with a yield of 51% and a rate of 3.5 g/L/h. They improved production by modifying 18 *E. coli* genes, including regulatory genes. PDO is also used as a polyglycol-like lubricant and as a solvent. Likewise, nylon has been traditionally made from a polymer of PDO. Another environmentally-friendly plastic is polylactide, made chemically from fermentation-derived L-lactic acid.

Improving efficiency is a major concern for the production of bioplastics. Only a few processes have emerged that actually use less energy in the production process. Therefore, researchers are still working on refining the processes used in order to make bioplastics viable alternatives to petrochemical plastics. Apart from energy use, other areas of concern are the sharing of agricultural space, since plants are also needed to fulfill the basic requirement of food, or as a raw material for other applications. Researchers are looking into creating a plant that can be used for food, but also as feedstock for plastic production. Transgenic corn engineered to produce bioplastics is currently under study. Eventually, it is hoped to engineer the plant in a way which would restrict plastic production to the stem and leaves of the plant. Hence, such plants would serve a dual purpose by providing food through the edible part while plastic could be extracted from the nonedible parts of the plant.

Xanthan gum was the first biopolymer to be made industrially and is the most significant microbial polymer. This polysaccharide was made at 90,000–100,000 metric tons in 2011 with a price of \$3–5 per kg. Ten to twenty thousand tons of xanthan are produced annually for use in the oil, pharmaceutical, cosmetic, paper, paint, and textile industries. Genetic manipulation has increased titers of xanthan by two-fold and increased pyruvate content, a desired characteristic, by 45%. Cloning genes, which complement xanthan-negative mutants, into wild-type *Xanthomonas campestris* increased xanthan production by 15%.

Cellulose is produced as an extracellular polysaccharide by a number of different bacteria in the form of microfibrils that can be used to produce molded materials of relatively high strength, such as high-fidelity loudspeaker cones and diaphragms.

Biopolymers having promising applications in wound healing are polysaccharides such as chitin, alginate, dextran, and hyaluronic acid. Although fungal cell walls form an important source of chitin and chitosan, these polymers are, at present, manufactured from sea food (shellfish) wastes. Researchers are trying to make use of intact fungal filaments as they prove to be an inexpensive source for wound dressings and other novel materials. Additional biopolymers, not previously available on a large scale, are now coming onto the market, thanks to biotechnology. One such example is hyaluronic acid, a polydisaccharide of D-glucuronic acid and N-acetyl glucosamine, found in the connective tissue matrices of vertebrates and also present in the capsules of some bacteria. Earlier, hyaluronic acid was produced by a laborious method using large quantities of rooster combs, while now, fermentation makes the process fast and efficient and obliterates the need of rooster combs.

1,3-Propane diol (1,3-PDO) produced by microbes is a non-toxic polyhydric alcohol used to produce polytrimethylene terephthalate, which is employed in the carpet industry, and to make highly durable and stain resistant textile fibers, thermoplastics, films, automobiles, apparel and coatings. Since the chemical processes are costly, 1,3-PDO is produced using biotechnology. Microbial production uses glycerol or glucose as the main substrate. Cell immobilization is an excellent way to produce 1,3 PDO from glycerol. Immobilized *K. pneumoniae* cells produced 83 g/L of 1,3 PDO, and *Clostridium butyricum* produced 93.7 g/L from pure

glycerol and 76.2 g/L from crude glycerol. The highest production was by recombinant *E. coli* at 104 g/L. In 2011, commercial production amounted to 153,600 tonnes. Chemical production by Shell Oil Co. amounted to 72,600 tonnes per year and by Evonik Degussa was 50,000 tonnes per year, the total representing 60% of the market. Biologically-produced 1,3-PDO by DuPont Tate and Lyle Bioproducts was at 66,000 tonnes or 33% of the total. Biological production generates 40% less greenhouse gas emissions than that from petrochemistry.

A group of biopolymers that particularly interest bio-technologists are proteins, because of their ability to utilize the new genetic manipulation techniques. Thus, genes for animal and plant proteins (e.g., collagen and various silks) can now be transferred into suitable microbial hosts and the proteins produced by fermentation. Defense services are interested in developing spider silk as a high-performance fiber for use in products such as bullet-proof vests.

Isoprene, a highly volatile liquid that can be polymerized to rubber, is presently made by chemical synthesis or extractively distilled from crude oil. However, these procedures require high pressure, consume too much energy and create pollution. It would be useful to be able to produce isoprene microbiologically. Engineering the methylerythritol 1-phosphate (MEP) pathway in *E. coli* resulted in the production of 19.9 mg/L isoprene.

Biofuels

Industrial biotechnology is heavily involved in the production of energy from renewable resources and biomass. Bioethanol is an alcohol made mainly from sugar and starch crops such as corn by fermenting the sugar components of biomass. Recent advances in technology make the cellulosic biomass of trees and grasses worth using as feedstocks for ethanol production. Waste matter such as agricultural residues from harvested crops, forestry wastes such as chips and sawdust from lumber mills, dead trees, and tree branches, municipal solid waste such as household garbage, and industrial wastes should be used as feedstocks for ethanol production besides energy crops (fast-growing trees and grasses such as switchgrass) developed for this purpose. Ethanol can be used as a fuel for cars in its pure form. In fact, Henry Ford's first car ran on ethanol. However, it is usually used as a gasoline additive (called E10, E15 and E85) to increase octane and improve vehicle emissions. These US motor fuels have 10–85% of ethanol derived from corn sugar.

The main components of biomass are cellulose, hemicellulose, and lignin. Two reactions important in the conversion of biomass into bioethanol are hydrolysis and fermentation. Starch, from corn, potatoes, sugarcane, and wheat, is used to produce ethanol as a substitute for gasoline. However, turning starch into ethanol is neither the most environmentally nor economically efficient method, as growing plants for ethanol production involves the use of herbicides, pesticides, fertilizers, irrigation, and machinery. Agricultural waste and cellulosic materials from trees and grasses seem to be a superior option as a feedstock for bioethanol production. A great deal of effort is concentrated on developing more effective bacterial cellulases that can break down agricultural waste into simple sugars to create a more plentiful and cheaper raw substrate for the production of ethanol.

Cellulose is a possible source of ethanol, but instead of containing only glucose, cellulose also contains C5 sugars such as xylose and arabinose. The best C5 utilizer is *Pichia stipitis* which can produce ethanol and clean up concentrated toxins liberated from lignocellulose degradation. It can produce ethanol from pretreated sources of biomass such as red oaks, wheat straw, sugarcane bagasse, rice straw, corn cobs, corn stover, aspen wood, pinewood, and poplar wood. From aspen wood chips, ethanol titer was 41 g/L with a yield of 0.47 g/g. In chemically-defined medium, 61 g/L can be made.

In 2005, the total world production of bioethanol was 46 billion liters. The producers of bioethanol are using a variety of microorganisms; the most favored being the yeast *S. cerevisiae* for large-scale fermentation processes. Researchers have also metabolically engineered the bacterium *Zymomonas mobilis* to augment its ability to ferment xylose and arabinose along with its innate ability of fermenting glucose. The purchase and pretreatment processing costs of the raw material feedstock govern the economy of bioethanol production processes. The most commonly used feedstocks, by far, have been corn and sugarcane, but alternative feedstocks rich in lignocellulose are required for sustainability and self-sufficiency of bioethanol production. Metabolic engineering is being used to develop production strains that can process the most abundant pentose sugar, that is, xylose, in hemicelluloses, hardwoods, and crop residues. This effort involves the introduction of key enzymes (xylose reductase, xylitol dehydrogenase, xylulokinase, or xylose isomerase) into ethanol-producing strains. Such metabolic engineering efforts have improved xylose consumption efficiency, with small decreases in growth rate and ethanol yield as compared with glucose utilization. Additional areas of bioethanol process development include identification of thermostable cellulases development of ethanologenic bacteria, and further metabolic engineering of *S. cerevisiae* to decrease formation of by-products, such as glycerol and organic acids. Bacteria such as the anaerobic and thermophilic clostridia could play a major role in the future production of bioethanol. *Clostridium thermocellum*, an anaerobic thermophile, converts waste cellulose (i.e., biomass) or crystalline cellulose directly into ethanol, without the need for fungal cellulase. A large amount of genetic work has been done on the clostridia and they are ready for a major application of rDNA technology to increase titers and ethanol tolerance, and to eliminate production of by-products, such as acetate and lactate.

The bacteria that naturally metabolize cellulose have gained much interest in recent years since they can utilize lignocellulosic waste and generate ethanol, a rare property among living organisms. Indeed, their cellulase systems mediate hydrolysis of lignin-containing materials, such as hardwood pretreated with dilute acid, as well as model substrates not containing lignin. In principle, the concept of anaerobic ethanol fermentation is a very simple one, that is, a single fermentation with five biologically mediated events involved in ethanol production: (1) cellulase and hemicellulase formation, (2) cellulose and hemicellulose hydrolysis, (3)

uptake of sugars and oligosaccharides, (4) hexose fermentation, and (5) pentose fermentation, all consolidated in a single process step. An advantage of such an anaerobic process is the reduced need for power-consuming agitation/aeration of reaction vessels for making biomass-degrading enzymes. Proponents of anaerobic thermophiles as ethanologens offer the following reasons: (1) thermophiles appear to be robust and contain stable enzymes; (2) anaerobes generally have a low cellular growth yield, hence more of the substrate can be converted to ethanol; (3) thermophilic fermentations run at 60°C are less prone to detrimental effects of contamination; (4) growth at higher temperatures may facilitate the removal and recovery of volatile products such as ethanol; (5) in situ cellulase production is much more economical than addition of cellulase; (6) rates of metabolism of cellulose and hemicellulose are high; and (7) a reduced need for power involved in cooling of fermentors.

Clostridia and other anaerobic bacteria break down cellulose with the formation of cellobiose and cellobioses as main products. The cellobioses and the cellobiose can be further utilized by the organism; indeed, the cellobioses are taken up more easily by *C. thermocellum* than the disaccharide. The final end products are ethanol, acetic acid, lactic acid, hydrogen, and carbon dioxide. The major economic obstacle is the production of the side-products acetate and lactate, which limits conversion yield. rDNA technology research is overcoming this bottleneck by inactivation of the genes encoding acetate- and lactate-producing enzymes.

Biofuel companies have already begun production of cellulosic ethanol. They include (a) DSM/Poet's plant in Emmetsburg, Iowa, expecting to produce 20 million gallons per year, (b) Beta Renewables in Crescentino, Italy, also a 20 million gallon/year operation. (c) Gran/Bio began production of cellulosic ethanol at 21 million gallons per year in San Miguel de Campos, Brazil. The cellulosic sources are agricultural wastes, i.e., straw and bagasse. It also uses technology from Beta Renewables, cellulase from Novozymes in Denmark, and yeast from DSM in Holland. (d) Abengoa opened its cellulosic ethanol plant in Hugoton, Kansas in October 2014. It is the largest one established so far, capable of producing 25 million gallons per year.

Ethanol can be produced from seaweed. The substrates are sugar from glucose, sulfated polysaccharides, mannitol, alginate, agar and carrageenan. Seaweeds contain low to zero levels of lignin, making carbon sources easier to use without delignification. They have a higher biomass productivity per year than lignocellulolytic biomass such as switchgrass, corn stover, Eucalyptus, poplar and willow. Fermentation of *Laminaria japonica* (brown sea weed) yielded 40 g/L of ethanol whereas that of *Gellidium elegans* (red seaweed) reached 55 g/L of ethanol.

Butanol is another alcohol which could help solve the problem of overdependence on petroleum as a motor fuel. Cloning of its *ace* operon genes *adc* (encoding acetoacetate decarboxylase), *ctfA*, and *ctfB* (two genes encoding coenzyme A transferase) on a plasmid containing the *adc* promoter into *Clostridium acetobutylicum* resulted in a 95% increase in production of acetone, a 37% increase in butanol and 90% increase in ethanol, a 50% increase in solvent yield from glucose, and a 22-fold lower production of acids. Elimination of acetone and ethanol production by genetic means could increase biobutanol production further and simplify purification.

Biodiesel is made up of fatty acid alkyl esters made from vegetable oils, animal fats or recycled greases. Biodiesel can be used as a fuel for vehicles in its pure form, but it is generally used as a petroleum diesel additive to reduce levels of particulates, carbon monoxide, hydrocarbons and air toxics from diesel-powered vehicles. Biodiesel, also known as biologically-derived diesel substitute, can be made from rapeseed (canola) or soybean oil, palm oil, jatropha, or recycled cooking oils by heating with a chemical catalyst. Animal fats, other vegetable oils, and other recycled oils can also be used to produce biodiesel, depending on their costs and availability. In the future, blends of all kinds of fats and oils may be used to produce biodiesel. The main reaction for converting oil into biodiesel is called transesterification. Genetically-modified bacteria can produce biodiesel from plant materials.

As is the case with bioethanol, biodiesel proves to be environmentally friendly as it can help make up for greenhouse gas emissions because it is produced from organisms that remove CO₂ from the atmosphere as a part of their natural metabolism. Biodiesel is a good alternative energy source and a substitute for petroleum-based diesel fuel. However, the current method of production is still not economical. Alexander Steinbuechel created a new form of biodiesel with colleagues at the University of Muenster in Germany. He and his group created a fuel-refining strain of *E. coli* by modifying it with genes taken from two other bacterial species. The modified *E. coli* strain was cultured in a mixture of glucose and the main constituent of olive oil, which it processed into a fatty acid diesel-substitute called microdiesel. The German team used two genes from the bacterium *Z. mobilis* to give *E. coli* the ability to produce alcohol from the sugar. A third gene, taken from the bacterium *Acinetobacter baylyi*, enabled the *E. coli* to then combine the alcohol with plant oils to produce microdiesel. Unlike regular biofuels, microdiesel is produced without toxic chemicals.

Genetic engineering has been utilized to produce biodiesel. The principal organisms for biodiesel fermentation are called "grease microorganisms," i.e., oleaginous microbes which supply fatty acids and alcohols and convert them to biodiesel. They include microalgae (*C. vulgaris*, *Botryococcus braunii*, *Navicula pelliculosa*, *Scenedesmus acutus*, *C. cohnii*, *Dunaliella primolecta*, *Monallanthus salina*, *Neochloris oleoabundans*, *Phaedactylum tricornutum* and *Tetraselmis sueica*). Genetic engineering has been used to convert the following into biodiesel producers: *E. coli* and *S. cerevisiae*. *E. coli* was converted into a biodiesel producer by overexpression of ethanol production genes from *Z. mobilis* and the wax ester synthase/acyl-CoA-diacylglycerol acyl transferase (WS/DGAT) gene from *A. baylyi* strain ADPI. Of potential importance are *Rhodococcus opacus* and *Y. lipolytica* for microbial biodiesel production, as well as cellulolytic microbes for biomass digestion, after plasmid insertion for FAEE production.

In 2010, 23 billion gallons of ethanol and 6 billion gallons of biodiesel were produced globally.

Renewable fuels and chemicals can also be produced using 2-keto acid-based biosynthetic pathways. 2,3-Butanediol (2,3-BD) (also known as 2,3-butylene glycol and dimethylene glycol) is a 4-carbon diol. They can be converted to the liquid fuel additive methyl ethyl ketone and also to 2,3-butadiene which is polymerized in the manufacture of synthetic rubber. Methyl ethyl ketone is also a good organic solvent for resins and lacquers. 2,3-BD can also be made at 83 g/L from crude glycerol (from the biodiesel

process) by *B. amyloliquefaciens* in the presence of beet molasses as co-substrate. The yield was 0.42 g/g and productivity was 0.87 g/L/h. Genomatica Inc (San Diego) has used their integrated biotechnology platform to develop an *E. coli* strain producing 120 g/L of 1,4-butanediol (BDO) from sugars. The rate of production is over 3 g/L/h.

Research is also exploring the engineering of an artificial microorganism which would be an ideal synthetic energy producer. This microorganism would be designed to produce excess hydrogen by depriving it of the genes required for sugar formation since they normally use hydrogen ions. Hence, the microorganism would devote all its energy toward excess hydrogen production.

Bioremediation

Bioremediation can be defined as any process that uses bacteria, fungi, green plants or their enzymes to return the environment altered by contaminants to its original condition. Bacteria that can degrade some soil contaminants, such as chlorinated hydrocarbons, are used in bioremediation. They are even employed in cleaning up oil spills, which is done by addition of nitrate and/or sulfate fertilizers, which helps in the decomposition of crude oil by bacteria. Genetic engineering facilitates creation of organisms specifically designed for bioremediation. The bacterium *Deinococcus radiodurans* (the most radioresistant organism known) has been engineered to digest toluene and ionic mercury from highly radioactive nuclear waste. Certain bacteria (cyanobacteria, pseudomonads, corynebacteria, and mycobacteria), green algae, and fungi (several molds and yeasts), can remove nearly 80% of hydrocarbons from oil spills within a short span of one year by oxidizing hydrocarbons at aerobic water/oil interfaces. Isolating or developing microbial strains capable of degrading and detoxifying hydrocarbon and halogenated hydrocarbon waste of industrial, agricultural, or military origin is essential in waste management. Understanding the role of microorganisms in the degradation and transformation of chemicals in the environment is a key factor in assessing the environmental safety of new and existing chemicals. Engineering microorganisms may solve contamination and recycling process problems. Another interesting role bacteria play is in recovering oils, minerals, and metals from their sources. Oil recovery may be facilitated by the development of unique bacteria which produce a surfactant that forces trapped oil out of rocks. Extraction of minerals from low-grade ores is enhanced by some bacteria (microbial leaching). In addition, selective binding of metals by biohydrometallurgical processes is important in recycling of metals such as silver and uranium.

Agricultural Biotechnology

Agricultural biotechnology, also referred to as green biotechnology, is biotechnology applied to agricultural processes. Since the advent of agriculture 10,000 years ago, farmers have used biological technology inadvertently in the refinement of methods of farming and crops through cross breeding, and various hybridization techniques. Later, the genetics of plants were modified by sophisticated plant breeding programs which resulted in the "Green Revolution." Thus, farmers were enabled to grow high-yield crops in order to satisfy the increasing food requirements of a growing population, and prevented starvation in many parts of the world. Today, using genetic engineering, scientists are able to produce plants with enhanced nutritional content, desired texture, color, flavor, growing season, yield, impart disease resistance, and improve other properties of production crops. Current agricultural research is focused on producing genetically engineered plants (transgenic plants). These are plants which contain one or more genes that have been artificially inserted instead of acquiring them through the natural process of pollination. Modern genetics assists in improving the growth, health, vigor, and other qualities of agriculturally important mammals, poultry and fish. With the advances in molecular biology, major areas of interest in plant biotechnology are plant tissue culture, plant genetic engineering, and plant molecular marker-assisted breeding. Conventional and rDNA technology help in improving microbial inoculants to be used to control plant pests, as fertilizer supplements, and to aid in atmospheric nitrogen fixation. Transgenic Bt corn is an outstanding example of successful application of genetic engineering in agriculture. It produces its own insecticide and contains a gene from the bacterium *Bacillus thuringiensis*. The use of Bt varieties has dramatically reduced the amount of chemical pesticides applied to cotton. Plants that have one or more foreign genes inserted, instead of their acquiring them naturally through pollination, are called genetically modified or GM crops. These crops are superior in terms of yields, herbicide tolerance, and pest-resistance, and have dominated agricultural biotechnology in the last decade. The most important transgenic crop planted is soybean, followed by corn, cotton, and canola. One of the biggest adversities farmers encounter in crop production is weed control, since there is a sharp reduction in crop yield and quality with poorly controlled weeds. Many GM crops are inserted with herbicide tolerance gene so that a broad-spectrum herbicide sprayed to the fields would kill all crops except the GM crops. Nutritionally-enhanced transgenic crops are produced using genetic engineering techniques. A striking example of this is Golden Rice, which is produced by inserting two genes from daffodil and one gene from a bacterium into rice plants so that the rice becomes capable of synthesizing beta-carotene, the precursor of vitamin A. This rice is produced with the aim of benefiting millions of people suffering from vitamin A deficiency, especially those living in developing countries.

Transgenic plants which are currently being developed are tomatoes, rice, canola grapes, tobacco, tea, coffee, and some trees. Transgenic tomato varieties with enhanced lycopene content and delayed ripening, to develop improved nutrition and flavor, are being developed. Transgenic canola with enhanced vitamin E levels is a subject being studied. Food crops engineered to produce edible vaccines against infectious diseases would make vaccination more child-friendly around the world. Bananas have received considerable research attention of late as a vehicle for vaccine delivery, because of their palatability and adaptation to tropical and

sub-tropical environments. Transgenic bananas are produced and are being evaluated for use as vehicles for cholera, hepatitis B and diarrhea vaccines. Some other GM crops being studied are decaffeinated tea and coffee and nicotine-free tobacco. To develop modified trees with reduced lignin content for the paper industry and the bioethanol industry is also an intriguing area of research in agricultural biotechnology.

Traditional biotechnological processes have applications in almost all spheres of life, ranging from pharmaceuticals to food production, industrial processes, waste and wastewater treatment, bioremediation, bio-leaching, biofuels, and biopolymers. These applications will undoubtedly continue, but recombinant DNA technology is expected to expand horizons of biotechnological research and industry and, at the same time, give insights for a more specific and controlled use of microbes and microbial products. Used efficiently, after appropriate risk assessment and with effective and enforced regulation, biotechnology has enormous potential to improve the quality of life and to enhance our capacity to conserve and protect the environment.

Glossary

cGMP cGMP refers to “current good manufacturing practice”, a set of regulatory principles designed for managing pharmaceutical manufacturing processes and facilities.

Fed-batch fermentation Fed-batch fermentation is used for high cell-density cultivation of recombinant cells. The fermentation begins with seeding cells in a fermentation medium in a bioreactor. The fermentation medium could be complex, enriched media (e.g., terrific broth) or defined media (e.g., phosphate-citrate broth, supplemented with chemicals such as carbon source and trace metals). Throughout the culture, the cells are fed with various nutrients, including a carbon source and nitrogen sources (such as amino acids). Usually, the feeds are concentrated so that the fermentation volume does not increase excessively.

Introduction

Glycosaminoglycans (GAGs) are naturally occurring polysaccharides, composed of alternating sugar units; these include an amino sugar (e.g., *N*-acetyl glucosamine, GlcNAc or *N*-acetyl galactosamine, GalNAc) and either a galactose (Gal) or an uronic acid (GlcA or IdoA) (Fig. 1). The carbon backbone of the GAG chain may undergo no further modifications (e.g., hyaluronan) or may be further modified through sulfation, de-acetylation, and/or epimerization (e.g., heparin, heparan sulfate, chondroitin sulfate, dermatan sulfate and keratan sulfate). Simple non-sulfated GAGs (e.g., hyaluronan) and the precursors of highly sulfated GAGs (e.g., heparosan and chondroitin) are produced in certain bacteria as well as in animals (Cress et al., 2014). These simple GAGs are thought to contribute to pathogenicity of the host bacteria. Simple, non-sulfated GAGs as well as the highly modified sulfated GAGs (e.g., heparin, heparan sulfate, chondroitin sulfate, dermatan sulfate and keratan sulfate) are produced in all animals, including humans. In humans, hyaluronan is part of the connective tissue extracellular matrix (ECM) and is involved in biological functions such as lubrication of joints. Highly sulfated GAGs have tissue-specific sulfated domains that are binding sites for various proteins (Capila and Linhardt, 2002) and, therefore, play critical roles in biological functions such as homeostasis, cell growth, cell migration, development, morphogenesis, tissue repair, and angiogenesis (Linhardt and Toida, 2004; Linhardt, 2003).

The current industrial production of GAGs can be broadly classified into three categories: (1) industrial production from animal source, (2) industrial production using microbial cells, and (3) industrial production using eukaryotes. Various GAGs have been routinely extracted and purified from animal sources, for example, hyaluronan from rooster combs, and heparin from pig intestines or bovine lung. An increased knowledge of GAG biosynthesis, as well as the advances in metabolic engineering strategies, bioprocess optimization, downstream processing approaches and analytical tools have led to the production of GAGs from microbial cells and exploration of eukaryotic cells, for example, CHO cells, toward heparin production.

Glycosaminoglycans

The glycosaminoglycan family includes: (1) hyaluronan (hyaluronate, hyaluronic acid); (2) heparin/heparan sulfate; (3) chondroitin/dermatan sulfate; and (4) keratan sulfate. Each GAG family has a common carbon backbone that can be variously modified (Table 1, Fig. 2) and may also have a variety of different molecular weight properties. The structural characterization of GAGs has been possible due to advances in biochemical and analytical tools, such as gel permeation chromatography, high-performance liquid chromatography (HPLC), ion-exchange chromatography, capillary electrophoresis, mass spectroscopy, and nuclear magnetic resonance (NMR) spectroscopy (Sun et al., 2016; Schlessinger et al., 2000; Xiao et al., 2010; Cai et al., 2013, 2012; Laremore et al., 2007; Fu et al., 2016; Zhang et al., 2015; Volpi et al., 2009; Moon et al., 2012; Edens et al., 1992; Desai et al., 1993; Yang et al., 2011; Kailemia et al., 2013; Li et al., 2014; Thanawiroon and Linhardt, 2003; Liu et al., 2014; Chen et al., 2017; Volpi et al., 2012; Thanawiroon et al., 2004; Zhao et al., 2013; Lohse and Linhardt, 1992; Leach et al., 2012; Guerrini et al., 2009; Wang et al., 1991; Mikhailov et al., 1997; Li et al., 2012). These analytical tools have aided GAG structural analysis and improved insight into the GAG structure-function relationships. In parallel, metabolic engineering tools, knock-in/out animal models and mammalian cell culture models, have also contributed to deciphering the GAG biosynthetic pathway and GAG functions (Lin et al., 2000; Sarrazin et al., 2011; Pönighaus et al., 2007; Xu and Esko, 2014; Esko and Selleck, 2002; Thacker et al., 2014; Bame and Esko, 1989; Bai and Esko,

Fig. 1 Building blocks of glycosaminoglycans (a) *N*-acetyl glucosamine, (b) *N*-acetyl D-galactosamine, (c) D-galactose, (d) D-glucuronic acid, and (e) L-iduronic acid. These sugar moieties may be further modified through the action of specific enzymes, such as *N*-deacetylases, sulfotransferases, and epimerases.

Table 1 Glycosaminoglycans

Type	Composition	Chemical Formula
Hyaluronan	Linear polymer of alternating D-glucuronic acid (GlcA) and N-acetylglucosamine (GlcNAc).	→4)β-D-GlcA (1→3) β-D-GlcNAc(1→, with no sulfation
Family of heparin, heparan sulfate and heparosan	Linear polymer of alternating D-glucuronic acid (GlcA) and N-acetylglucosamine (GlcNAc). Heparosan is modified through the actions of tissue specific sulfotransferases, epimerases to form heparan sulfate and heparin.	→4) β-D-GlcA or α-L-IdoA(1→4) β-D-GlcNAc/S(1→, with sulfation
Family of chondroitin sulfate and dermatan sulfate	Linear polymer of alternating D-glucuronic acid (GlcA) and N-acetylglucosamine (GalNAc). Chondroitin modified through the actions of tissue specific sulfotransferases to form chondroitin sulfate; dermatan sulfate is sulfated as well as the GlcUAGlcA moiety of dermatan sulfate is epimerized into iduronic acid.	→4) β-D-GlcA or α-L-IdoA(1→3) β-D-GalNAc(1→, with sulfation
Family of keratan sulfate	Linear polymer of alternating galactose (Gal) and N-acetylglucosamine (GalNAc), with sulfation, for example, sulfation at the carbon 6 of galactose and N-acetylglucosamine.	→3) β-D-Gal (1→4) β-D-GalNAc(1→, with sulfation

1996; Aikawa et al., 2001; Fuster et al., 2007; Grobe et al., 2002; Bame et al., 1991). For example, metabolic engineering of suspension CHO cells through the up-regulation of exogenous Golgi-targeted 3OST1 revealed formation of distinct antithrombin binding sites; antithrombin binding sites directly correlate to anticoagulant activity of CHO derived engineered HS (Datta et al., 2013). Metabolic engineering tools together with analytical tools synergistically contribute to GAG research.

Hyaluronic Acid

Hyaluronan (hyaluronic acid; hyaluronate) is a naturally occurring non-sulfated glycosaminoglycan (GAG), composed entirely of alternating GlcA and GlcNAc moieties (Table 1, Fig. 2) (Vigetti et al., 2014). Hyaluronan synthase (HAS) polymerizes linear HA polysaccharide from UDP-sugars by adding alternating GlcNAc and GlcA moieties to the growing HA carbon chain (Vigetti et al., 2014; Bodevin-Authelet et al., 2005; Fraser et al., 1997; O'Regan et al., 1994; Itano and Kimata, 2002; Itano et al., 1999). HAS enzymes occur in certain bacteria as well as mammals. *Streptococcus* sp., such as *S. zooepidemicus* express bacterial HAS and biosynthesize hyaluronan (O'Regan et al., 1994; Hascall et al., 2016; DeAngelis, 2015) which aids in bacterial pathogenesis.

Cellular biosynthesis of hyaluronan in mammalian cells occurs through the action of a family of hyaluronan synthases (HAS1-3), which are found in the plasma membrane (Itano and Kimata, 2002). In humans, hyaluronan is synthesized primarily in mesenchymal cells (e.g., fibroblasts, endothelial cells); however, it is found on the cell surfaces in many tissues. In humans, hyaluronan has several important roles (Hascall et al., 2016). It forms a vital constituent of the extracellular matrix and connective tissue systems, including, skin, synovial fluid in the joints, vitreous humor of the eye, heart valve, lungs, and umbilical cord (Vigetti et al., 2014; Bodevin-Authelet et al., 2005; Fraser et al., 1997; Itano and Kimata, 2002; Hascall et al., 2016; Robert et al., 2010; Inatani and Tanihara, 2002; Carrino et al., 2000; Oksala et al., 1995; Temple-Wong et al., 2016). Due to its physicochemical properties, hyaluronan can provide a framework for cell migration and is capable of retaining moisture (Papakonstantinou et al., 2012). Aging skin shows reduced expression of GAGs including hyaluronan and reduced moisture retention (Papakonstantinou et al., 2012). Reduced hyaluronan expression and activity in part correlates with decreased HAS1, increased hyaluronan lyases (HYAL1-3), and decreased hyaluronan receptors (CD44 and RHAMM).

A number of medical and personal care applications for exogenous hyaluronan have been developed in recent years with research ongoing, many to address physiological and pathological changes that occur with aging. Hyaluronan has been used in skin-cosmetics (Carrino et al., 2000; Naylor et al., 2011; Tzellos et al., 2009; Anderegg et al., 2014; Oh et al., 2011). Due to its

Fig. 2 Sugar moiety backbone of glycosaminoglycans (A) hyaluronan, (B) family of heparin, heparan sulfate and heparosan, (C) family of chondroitin and chondroitin sulfate, (D) dermatan sulfate, (E) family of keratan sulfate, and (F) sugar moieties, namely, glucuronic acid (GlcA), N-acetylglucosamine (GlcNAc), N-acetylglucosamine (GalNAc), galactose (Gal), and Iduronic acid (IdoA). Hyaluronan (A), heparosan (B), and chondroitin (C) are unmodified linear sugar moiety backbone chains. Keratan sulfates (E) have O-sulfated galactose and N-acetylglucosamine moieties. The sugar moieties of heparosan (GlcA and GlcNAc) may be further modified through actions of tissue-specific N-sulfotransferases, C5 epimerases and O-sulfotransferases, to form sulfated heparin and heparan sulfate. The sugar moieties of chondroitin (GlcA and GalNAc) may be further modified through actions of tissue-specific O-sulfotransferases, to form sulfated chondroitin sulfate. The sugar moieties of chondroitin (GlcA and GalNAc) may be further modified through actions of tissue-specific epimerases (that transform GlcA to IdoA), and O-sulfotransferases, to form sulfated dermatan sulfate. Figures were drawn from Cheng, K., Zhou, Y., Neelamegham, S., 2017. DrawGlycan-SNFG: A robust tool to render glycans and glycopeptides with fragmentation information. *Glycobiology* 27 (3), 200–205.

mucoadhesive behavior and contribution to the elastoviscous behavior of soft connective tissues, for example, in synovial fluid in the joints and vitreous humor of the eye (Robert et al., 2010; Nishida et al., 1991; Yokoi et al., 1997), hyaluronan has been used in eye drops to lengthen the pre-corneal retention time (Salzillo et al., 2016). The synovial fluid of the joints is majorly composed of hyaluronan and functions in lubrication and knee movement. During osteoporosis, cartilage degradation in joint and reduced synovial fluid results in pain and reduced movement. High molecular weight (1.0–2.9 million Dalton) ultra-pure hyaluronan has

been utilized to treat pain in osteoarthritis of the knee. Other applications of hyaluronan include wound healing (Oksala et al., 1995), a potential marker for tumors or cancers (Stern, 2009), a drug delivery vehicle (Brown and Jones, 2005), and a biomaterial scaffold for tissue engineering (Dicker et al., 2014; Shu et al., 2004). Currently, hyaluronan is used in a variety of pharmaceutical products including Euflexxa, Healon, Synvisc, Orthovisc, Septrafil, and Restylane (Hascall et al., 2016; DeAngelis, 2015; Schiraldi et al., 2010; Boeriu et al., 2013; Cimini et al., 2017).

Heparin and Heparan Sulfate

Heparin and heparan sulfate are naturally occurring, sulfated GAGs composed of alternating GlcA and GlcNAc moieties (Table 1, Fig. 2). During their biosynthesis, these GAGs are modified through the action of specific enzymes, *N*-deacetylases, sulfotransferases, and epimerases (Carlsson and Kjellén, 2012; Garg et al., 2005). Heparan sulfate is present on cell surfaces and binds to various protein ligands, resulting in the regulation of a variety of biological processes such as cell growth and angiogenesis. Heparin is predominantly present in mast cells and is commercially used as a biopharmaceutical anticoagulant drug (Carlsson and Kjellén, 2012; Garg et al., 2005).

In humans, heparan sulfate/heparin are biosynthesized as proteoglycans, attached to specific core proteins, such as syndecan, glypican, and serglycin. Heparan sulfate/heparin share a similar biosynthetic pathway. Biosynthesis begins with the formation of a tetrasaccharide linker -xylose-galactose-galactose-GlcA on serine residues of the core protein. Next, α -*N*-acetyl glucosaminyl transferase adds α -GlcNAc to the non-reducing terminal GlcA of this tetrasaccharide linker. The family of EXT enzymes (Exostoses, EXT1-2) sequentially add GlcNAc and GlcA, forming a linear non-sulfated heparosan polysaccharide (Lin et al., 2000; Busse et al., 2007; Wuyts et al., 1998; Okada et al., 2010). The heparosan chain is modified through the action of various sulfotransferases and epimerases to produce sulfated heparan sulfate and highly sulfated heparin. Briefly, the GlcNAc residues are *N*-deacetylated and *N*-sulfated by a family of *N*-deacetylase/*N*-sulfotransferase (NDST) enzymes to form GlcNS (Saribas et al., 2004). The GlcA residues may be epimerized into IdoA by C5-epimerase (GLCE) enzymes (Feyerabend et al., 2006) and the uronic acid residue *O*-sulfated by 2-*O*-sulfotransferase; the GlcNS moieties may be *O*-sulfated by families of 6-*O*-, and 3-*O*-sulfotransferases (Moon et al., 2012; Carlsson and Kjellén, 2012; Garg et al., 2005; Anower-E-Khuda et al., 2013; Sasisekharan and Venkataraman, 2000). There are tissue-specific isoforms of the NDSTs and *O*-sulfotransferases, and these generate tissue-specific sulfated domains. The 3-*O*-sulfotransferase isoform-1 (3OST-1), for example, is critical for the production of anticoagulant heparin and is present in mast cells, which chiefly biosynthesize anticoagulant heparin (Forsberg et al., 1999). Heparan sulfate is characterized by partially sulfated domains, and these domains provide the specific ligand binding characteristic to heparan sulfate, for example, cell growth, cell development, angiogenesis, and metastasis (Sarrazin et al., 2011). Heparin is characterized by completely, or nearly completely sulfated domains, and has specific antithrombin III (ATIII)-binding sites. The ATIII-binding site of the heparin interacts with antithrombin (AT; a serine protease inhibitor). This interaction leads to a conformational change in the AT and amplifies inhibition of thrombin (factor IIa) and factor Xa via the action of AT. This results in anticoagulation and use of heparin as an anticoagulant drug (Onishi et al., 2015).

Chondroitin Sulfate and Dermatan Sulfate

Chondroitin/dermatan sulfate belong to a family of naturally occurring linear, sulfated GAGs made of repeating sugar moieties, namely GlcA and GalNAc residues (Tables 1 and 2, Fig. 2). Chondroitin sulfate/dermatan sulfate in higher animals are highly sulfated, and the sulfated domains act as ligands for proteins and mediate biological functions.

In humans, chondroitin sulfate-type A (e.g., CSA) is predominant in connective tissues and ECM, for example, cartilage, cornea, bone, skin, arterial walls. Chondroitin sulfate provides a framework, and promotes elasticity in cartilage. These properties have made chondroitin sulfate-type A a popular dietary supplement. Dermatan sulfate is predominant in skin, heart valve, tendons, and

Table 2 Disaccharide units of chondroitin sulfate and dermatan sulfate

CS/DS	Major disaccharide units and their sulfation pattern	Chemical formula
Chondroitin (CS-DS)	Unsulfated glucuronic acid and unsulfated <i>N</i> -acetylgalactosamine	$\rightarrow 4) \beta\text{-D-GlcA}(1\rightarrow 3)\text{-}\beta\text{-D-GalNAc}(1\rightarrow$
Chondroitin sulfate A (CS-A); chondroitin-4-sulfate	Unsulfated glucuronic acid and <i>N</i> -acetylgalactosamine sulfated at carbon 4	$\rightarrow 4) \beta\text{-D-GlcA}(1\rightarrow 3)\text{-}\beta\text{-D-GalNAc4S}(1\rightarrow$
Dermatan sulfate (CS-B)	L-iduronic acid and <i>N</i> -acetylgalactosamine sulfated at carbon 4	$\rightarrow 4) \alpha\text{-L-IdoA}(1\rightarrow 3)\text{-}\beta\text{-D-GalNAc4S}(1\rightarrow$
Chondroitin sulfate C (CS-C); chondroitin-6-sulfate	Unsulfated glucuronic acid and <i>N</i> -acetylgalactosamine sulfated at carbon 6	$\rightarrow 4) \beta\text{-D-GlcA}(1\rightarrow 3)\text{-}\beta\text{-D-GalNAc6S}(1\rightarrow$
Chondroitin sulfate D (CS-D); chondroitin-2,6-sulfate	Glucuronic acid sulfated at carbon 2 and <i>N</i> -acetylgalactosamine sulfated at carbon 6	$\rightarrow 4) \beta\text{-D-GlcA2S}(1\rightarrow 3)\text{-}\beta\text{-D-GalNAc6S}(1\rightarrow$
Chondroitin sulfate E (CS-E); chondroitin-4,6-sulfate	Unsulfated glucuronic acid and <i>N</i> -acetyl galactosamine sulfated at carbon 4 and 6	$\rightarrow 4) \beta\text{-D-GlcA}(1\rightarrow 3)\text{-}\beta\text{-D-GalNAc4S6S}(1\rightarrow$

blood vessels. Chondroitin sulfate/dermatan sulfate also play regulatory roles in cell proliferation, cell development, cell adhesion, homeostasis, cardiovascular disease, tumorigenesis, infection, wound repair and fibrosis (Hardingham, 1998; Maeda et al., 2011; Linhardt and Hileman, 1995; Sugahara and Mikami, 2007; Uebelhart, 2008; Vallières and du Souich, 2010). In addition, dermatan sulfate may form complexes with heparin cofactor II, and may act as an anticoagulant. Chondroitin sulfate proteoglycans are potential targets for malaria vaccines (Dinglasan et al., 2007) as *Plasmodium falciparum* (the dominant African malaria parasite)-infected erythrocytes express proteins, such as variant surface antigen 2-CSA that bind to chondroitin sulfate A and mediate malarial pathogenesis. Commercial applications for both chondroitin sulfate/dermatan sulfate have been growing, such as the use of chondroitin sulfate in bone repair and dermatan sulfate in wound repair. Other applications of chondroitin sulfate, with other biopolymers such as hyaluronan and collagen, include designing slow and controlled biodegradable scaffolds for wound healing.

In humans, chondroitin sulfate also exists as proteoglycans, synthesized and attached to specific core proteins (Mikami and Kitagawa, 2013). Like heparan sulfate/heparin, the biosynthesis of chondroitin sulfate begins with the formation of the tetrasaccharide linker xylose-galactose-galactose-GlcA on serine residues of the core protein. Next, a β 1–4 linked GalNAc is added to the non-reducing GlcA. Chondroitin synthase sequentially adds GalNAc and GlcA, forming a linear non-sulfated chondroitin. The polysaccharide-backbone is further modified through the action of various sulfotransferases to produce sulfated CS. Epimerization of GlcA into IdoA and subsequent sulfation of sugar moieties results in dermatan sulfate (Table 2).

Keratan Sulfate

Keratan sulfates are naturally occurring linear sulfated GAGs made of repeating Gal and GlcNAc residues (Table 1, Fig. 2) (Pomin, 2015). The polysaccharide chain can be further modified through the action of 6-O-sulfotransferases (GlcNAc6ST) that act on both the GlcNAc and Gal moieties (Uchimura, 2015). Keratan sulfate is an important ECM component and has been found in cornea, cartilage, and brain (Funderburgh, 2000).

Industrial Production of Glycosaminoglycans: Current State and Future Directions

Industrial scale production of commercially relevant GAGs can be broadly grouped as (1) production from animal sources, (2) production from cultured microbial cells, and (3) production from cultured eukaryotic cells (Schiraldi et al., 2010; Boeriu et al., 2013; Cimini et al., 2017).

Industrial Production of GAGs From Animal Sources

Industrial production of GAGs from animal sources is performed for industrial production of hyaluronan, heparin, and chondroitin sulfate. GAGs are abundant in animal tissue. Specific animal tissues have been used for GAG extraction, for example, (1) hyaluronan from rooster combs and bovine/porcine eyes, (2) chondroitin from animal cartilage, (3) dermatan sulfate from mucosal tissue and animal hide/skin, and (4) heparin from porcine/bovine mast cells that are found in intestine and lung tissues. The extraction of GAGs is performed in non-cGMP slaughter houses (Boeriu et al., 2013). The extracted GAGs are then purified in cGMP facilities. However, concerns such as the presence of undesirable animal products and contamination risks (viruses, prions) have motivated development of methods for industrial production of GAGs through fermentation or cell culture (Fu et al., 2016). In addition, the ability to create tailored GAGs with specific or novel functionality creates another impetus for controlled production (Oduah et al., 2016).

Industrial Production of GAGs From Microbial Sources

Certain bacteria have the necessary enzyme machinery for producing simple, non-sulfated GAGs, such as hyaluronan, heparosan, and chondroitin (Fig. 3). Industrial production of GAGs from microbial sources is performed for production of hyaluronan from *Streptococcus* sp. and chondroitin sulfate from *E. coli* K4.

Hyaluronan is a simple non-sulfated GAG. Bacteria such as the gram-positive *Streptococcus* sp. and gram-negative bacteria *Pasteurella multocida*, can naturally produce hyaluronan (Schiraldi et al., 2010; Cimini et al., 2017). The hyaluronan exists in the mucoid capsule of these bacteria and aids in the pathogenicity. In *S. zooepidemicus*, genes required for the hyaluronan biosynthesis are encoded in the HAS operon (*hasA*, *hasB*, *hasC*, *hasD*, and *hasE*) (Table 3). In the presence of magnesium ions (e.g., $MgCl_2$), bacterial HAS enzymes polymerize the hyaluronan chain using UDP-GlcNAc and UDP-GlcA as substrates. Under certain conditions, the *S. zooepidemicus* may produce 6–7 g/L of hyaluronan. The hyaluronan from the fermentation broth is recovered using ultrafiltration, and precipitation with chemicals such as cetylpyridinium chloride. The final product is sterilized and tested for activity and endotoxin levels. Recent advances in exploring alternative bioengineered microbial hosts toward hyaluronan production include *E. coli*, *Bacillus* sp., *Agrobacterium* sp., and *Lactobacillus lactis*. *Escherichia coli* JM109 co-expressing two genes, pmHas gene from *P. multocida* and kfiD gene from *E. coli* K5 strain, was able to produce 0.5 g/L hyaluronan in shake-flask culture. The fed-batch fermentation and optimization of fermentation parameters, such as the addition of glucosamine supplements, led to the production of 2.0–3.8 g/L hyaluronan in fed-batch fermentation using the bioengineered *E. coli* JM109 strain. *L. lactis*, co-expressing genes *hasA*, *hasB*, and *hasC* from *S. zooepidemicus*, was able to produce 1.8 g/L hyaluronan in a batch bioreactor. *Agrobacterium* sp. ATCC

Table 3 Hyaluronan biosynthesis genes in bacteria *Streptococcus zooepidemicus*

Hyaluronan genes	Gene (product) and function
<i>hasC</i>	<i>hasC</i> (gtaB, UDP-glucose pyrophosphorylase) is required for conversion of glucose–1-phosphate to UDP-glucose
<i>hasB</i>	<i>hasB</i> (tuaD, UDP-glucose dehydrogenase) is required for conversion of UDP-glucose to UDP-glucuronic acid
<i>hasE</i>	<i>hasE</i> (pgl, phosphoglucosyltransferase) is required for reversible conversion of glucose–6-phosphate to fructose–6-phosphate
<i>hasD</i>	<i>hasD</i> (gcaD, Acetyl transferase/UDP-GlcNAc pyrophosphorylase) is required for conversion of GlcN–1-P to UDP-GlcNAc
<i>hasA</i>	<i>hasA</i> (hyaluronan synthase) is required for polymerization of UDP-GlcA and UDP-GlcNAc

31749, co-expressing *pmHAS* gene from *P. multocida* and the *kfiD* gene (encodes UDP-glucose dehydrogenase) from *E. coli* K5 strain, was able to produce 0.3 g/L hyaluronan in shake-flask cultures.

Industrial production of sulfated GAGs, such as chondroitin sulfate and heparin would require production of chondroitin or heparosan, respectively, in bacteria, followed by purification and subsequent chemoenzymatic synthesis of chondroitin sulfate and heparin. Certain bacteria, for example, *E. coli* K4 and *E. coli* K5, are able to synthesize chondroitin and heparosan, respectively (Cress et al., 2013a,b). Bacterial chondroitin and heparosan are part of their capsular polysaccharides.

Recently, industrial production of food grade chondroitin sulfate from microbial fermentation of *E. coli* K4 has been developed (see Relevant Websites section). Briefly, *E. coli* K4 fermentation and subsequent purification produced crude chondroitin sodium. Regioselective sulfation of the chondroitin sodium, followed by purification produced chondroitin sulfate sodium (Mythochondro™). In a parallel experiment, metabolic engineering of *E. coli* BL21 Star™ (DE3) strain with ePathBrick vector, encoding K4 CS-O genes, namely, *KfoF*, *KfoA* and *KfoC*, resulted in 2.4 g/L in a fed batch fermentation (He et al., 2015).

Production of pharmaceutical heparin is estimated at almost 100 metric tons annually, with an annual sale of over \$3 billion (Fu et al., 2016; Onishi et al., 2015). Currently, pharmaceutical heparin is extracted and purified from pig or cow mucosal tissues. Animal-sourced heparin production begins in non-cGMP animal slaughterhouses, followed by extraction and purification in cGMP facilities. However, concerns such as extraction of heparin in non-cGMP slaughterhouses, contamination risks (virus, prions), and the possibility of adulteration in sites not under USFDA or EMEA supervision, have necessitated alternate routes for heparin production (Fu et al., 2016). Understanding the heparin biosynthetic pathway and the key enzymes required for biosynthesis of heparin has provided strategies for industrial production of heparin from non-animal sources, such as chemoenzymatic synthesis of heparin from microbial heparosan and metabolic engineering of mammalian cells (Cai et al., 2013; Fu et al., 2016; Bhaskar et al., 2015, 2012; Masuko and Linhardt, 2012; Higashi et al., 2011; Wang et al., 2010, 2011; Jin et al., 2016). Knock-in and knock-out animal- and cell-culture studies demonstrated that HS/HP enzymes, NDST2, 2OST, C5epi (GLCE), 6OSTs and 3OST1 are important for the production of antithrombin binding sites on heparin (Fig. 4) (Lin et al., 2000; Pönighaus et al., 2007; Esko and Selleck, 2002; Bame and Esko, 1989; Bai and Esko, 1996; Aikawa et al., 2001; Bame et al., 1991; Gasimli et al., 2014). The chemoenzymatic synthesis of heparin uses microbial systems for the production of heparin precursors (i.e., heparosan) followed by chemoenzymatic modification using chemicals and/or the critical enzymes NDST2, 2OST, GLCE, 6OSTs, and 3OST1. For example, bacteria such as *Pasteurella multocida* type D strain and *E. coli* K5 naturally produce capsular heparosan (Wang et al., 2010, 2011; Chavarroche et al., 2012). Production of heparosan in *P. multocida* type D strain involves sequential addition of GlcNAc and GlcA, through the actions of glucosyltransferases (PmHS1) (Chavarroche et al., 2012). Production of heparosan in *E. coli* K5 involves sequential addition of GlcNAc and GlcA, through the actions of glucosyltransferases (KfiA and KfiC) (Wang et al., 2010, 2011). Fermentation process optimization in *E. coli* K5 in a fed-batch fermentation in a glucose-based defined medium at 37°C, with 30% dissolved oxygen, resulted in 15 g/L crude heparosan (Wang et al., 2010, 2011). Recently, researchers have metabolically engineered an *E. coli* BL21 strain with *E. coli* K5 glucosyltransferases and demonstrated heparosan production in the engineered BL21 strain

Biosynthesis of heparan sulfate: Coordination of polymer-modification reactions in a Chinese hamster ovary cell mutant defective in N-sulfotransferase. *Journal of Biological Chemistry* 266 (16), 10287–10293; Datta, P., Li, G., Yang, B., et al., 2013. Bioengineered Chinese hamster ovary cells with golgi-targeted 3-O-sulfotransferase-1 biosynthesize heparan sulfate with an antithrombin-binding site. *Journal of Biological Chemistry* 288 (52), 37308–37318; Gasimli, L., Glass, C.A., Datta, P., et al., 2014. Bioengineering murine mastocytoma cells to produce anticoagulant heparin. *Glycobiology* 24 (3), 272–280.

(Zhang et al., 2012). The heparosan thus obtained from microbial sources, could be modified chemoenzymatically to produce anticoagulant heparin (Bhaskar et al., 2015). In another approach, mammalian cells, such as CHO cells which naturally produce heparan sulfate, could be metabolically engineered toward the production of heparin (Baik et al., 2012).

Optimization of GAG production in bacteria requires availability of genome sequence combined with advances in analytical and metabolic engineering tools. Genome sequencing has revealed gram-positive and gram-negative bacteria capable of producing simple non-sulfated GAGs, such as hyaluronan, chondroitin and heparosan. The biosynthesis of hyaluronan, heparosan and chondroitin share a carbon source that is also required for maintaining cell growth and biosynthesis of cell wall components. For example, glucose, the precursor for GlcNAc and GlcA, is utilized for the biosynthesis of glucose-6-phosphate (Fig. 3). The glucose-6-phosphate is utilized for cell growth via glycolysis and the pentose phosphate pathway, as well as biosynthesis of cell wall components (Wang et al., 2011). Commercial production of GAGs from bacterial sources will require studies on metabolic control analysis and metabolic flux analysis. These methods may be utilized to evaluate correlations between cell metabolism and GAG production, in response to internal cues (e.g., genetics) and external cues (e.g., media composition). For example, it has been postulated that UDP-glucose 6-dehydrogenase and production of UDP-GlcA could be limiting factors for GAG biosynthesis. High throughput gene screening may reveal genes that steer metabolites toward production of GAGs without affecting cell growth. ePathbrick (Xu et al., 2012) vectors have been used to metabolically engineer a chondroitin pathway in BL21, resulting in CS yield comparable to CS produced from *E. coli* K4 (2.9 g/L) (He et al., 2015; Xu et al., 2012; Zhao et al., 2015; Xu and Koffas, 2013). In parallel, CRISPathBrick (Cress et al., 2015) can be utilized to tune expression of exogenous genes and repress endogenous genes in *E. coli* (Cress et al., 2015).

Conclusion

The medical and non-medical uses of GAGs (e.g., heparin, hyaluronan, chondroitin sulfate, dermatan sulfate) have led to a need for industrial-scale production of GAGs from Generally recognized as safe (GRAS) organisms. Collaborative research toward the improvement of current strains that produce simple GAGs, exploring new organisms (bacterial, simple eukaryotes, and mammalian systems, such as CHO cells), as well as improvement and development of analytical and metabolic engineering tools will play significant roles in the industrial production of simple and complex GAGs.

Infectious Waste Management[☆]

A Albiñ, National Veterinary Institute, Uppsala, Sweden

© 2019 Elsevier Inc. All rights reserved.

Glossary

Animal by-products (ABP) Any part of an animal carcass, or any material of animal origin, not intended for human consumption.

Biowaste (BW) Biological waste from human, animal, or plant origin as from toilets, households, restaurants, animal production, slaughter houses, food, and beverage industry, and so forth.

BSE Bovine spongiform encephalopathy, the mad-cow disease.

Emerging diseases New, reemerging, or drug-resistant infections with increasing incidence.

Pathogen pollution Spread of pathogens in the environment owing to the use of BW or due to other reasons.

Vector animals Insects, birds, and some wild mammalian species that transfer pathogens, directly or indirectly, to animals and humans.

Zoonoses Diseases and infections that are naturally transmitted between vertebrate animals and man.

Abbreviations

ABP	Animal by-products
BSE	Bovine spongiform encephalopathy;
BW	Biowaste
EFSA	European Food Safety Authority
FMD	Foot and mouth disease
VTEC	Verotoxin-producing <i>Escherichia coli</i>

Defining Statement

Incineration or landfilling of infective waste is almost a safe solution in the context of biosecurity. However, the desire to move toward a sustainable society is increasing the interest in recycling today. Treatment options for biological waste vary in their sanitization effect. After application to land, in fertilization purpose, some pathogens may persist in the environment for extended periods of time.

Sources of Infectious Waste

Biological Waste

Biological waste (BW) may be of agricultural, municipal, or industrial origin and must always be assumed to contain infectious agents of human, animal, or plant origin. It is debatable whether manure, sewage sludge, and several other BW should be classified as a waste or as a resource. However, concerning the biosecurity aspects and handling and treatment regimes, the considerations are very much the same as for BW in general, and therefore these products are classified as BW here.

Agriculture is a large producer of BW, both of animal origin, such as manure and animal by-products (ABP), and of plant origin, such as residues from harvest, animal feed residues, and plant material from greenhouses. In some regions, fish farming may also produce large amounts of BW. The definition and handling of ABP have been of special interest since the problem with bovine spongiform encephalopathy (BSE), or the mad-cow disease, became widespread in Europe during the 1990s. According to the present EU legislation (EC 2011/142), in Europe, ABP is divided into three risk categories depending on the risk of presence of prions and other pathogens, with different treatments prescribed for different categories. Category 1 ABP, the highest risk category, includes mainly material from ruminants, which may be suspected to be infected with prions. Category 2 includes, for example, carcasses of animals other than ruminants and manure for sale. Category 3 is mainly low-risk slaughterhouse waste.

[☆]*Change History:* July 2014: A. Albiñ introduced small edits in the text of the article and added a few more references in 'Further Reading' section, and added new Figures 2–6.

This article is an update of A. Albiñ, Infectious Waste Management, *Encyclopedia of Microbiology* (3rd Edn), edited by Moselio Schaechter, Academic Press, 2009, pp. 500–512.

Municipal sewage treatment plants produce huge amounts of sewage sludge, but other handling systems for toilet waste also produce voluminous quantities of BW. Other origins of BW may be categorized as ABP from handling, preparation, and consumption of food, for example, from grocery stores, households, restaurants, and schools, and from international transport and trade. BW of plant origin comes from gardens, park areas, and so on as well as from food handling and production.

Origin of industrial BW is mainly the food and beverage industry. Another large source of BW is the technical industry, which make use of products of biological origin, such as the tanning industry and the production of industrial fat. When such BW is of animal origin, it should be treated and handled as ABP.

Mixing of BW and Nonorganic Compounds

Concerning recycling and the society's efforts to achieve a balanced interplay between urban and rural areas, it is beneficial if BW and other waste products are sorted so that they can be appropriately treated. Proper BW is much easier to process and recycle than BW contaminated with nonorganic compounds. However, source separation of BW is not always performed or even when performed may be unsuccessful. BW from sources lacking professional source separation, for example, households and public places, is often mixed with nonorganic compounds. Another example is the effluents from toilets, as sewage is a mixture containing many contaminants. Spreading of information and education may be beneficial for successful source separation of solid waste and for treatment of effluents of toilet systems, and the quality of the end product may increase. Separation of mixed wastes at a processing facility may also be possible followed by treatments for potential recycling, although this will increase the overall cost of treatment. Another way to handle the problem of mixed waste is to process the BW first by, for example, composting, followed by separation of nonorganic compounds. However, the end product may be of low quality, concerning its use on arable land. Mixed types of solid wastes that cannot be recycled and that are not suitable for incineration must be land-filled in a safe way. Sewage is often a mixture of BW, industrial effluents, and stormwater from streets, and so on and therefore rather complicated to handle and recycle. Agricultural use may lead to pollution of soil with heavy metals, nonorganic substances, and other unwanted substances.

Health Risks from Pathogens in BW

Infections in BW Can Be More or Less Severe

It must be assumed that almost all kinds of pathogens may be present in BW and that BW is therefore potentially hazardous to animal and human health. Most pathogens found in BW originate from human or animal feces. Sewage sludge and manure reflect the health status of a population and have in some studies been used as an easy way to get fecal samples from large populations. A broad spectrum of pathogens can be found in toilet waste, but the severity of gastrointestinal infections varies. Diarrhea is one of the most common causes of death worldwide, especially among children. In developing countries, infectious diseases of both humans and animals are more common than in developed countries, resulting in a heavy load of pathogens in BW. Pathogens that are rare in the developed world may be commonly seen in developing countries, parasitic diseases being of special interest. Infectious diseases are now spreading geographically much faster than at any previous time. Owing to intensive travel and trade, an epidemic or epizootic disease outbreak in any part of the world is not far from becoming a threat somewhere else. Exotic infections can quickly spread across borders and even across continents. The vulnerability is universal, and globalization increases the possibility of new pathogens being spread by BW. From high-density livestock areas or areas of intensive agriculture, excess manure, plant residues, and so on may have to be transported to other areas to be used as fertilizers. This involves a considerable increase in the biosecurity risk, as diseases not indigenous to a region may be introduced.

We have to also consider and handle both known and unknown diseases. New diseases may arise from nowhere, and well-known diseases may change in character concerning severity, epidemiology, incidence, and other characteristics. Furthermore, just about half of the bacteria in the human intestine and most of the environmental bacteria have not yet been cultured or characterized.

Exposure to Pathogens Originating from Infective Waste

Direct exposure to infective agents in BW may occur at collection, transport, treatment, storage, use, and in other ways of BW. When these are in the hands of well-educated professionals who use suitable personal protective equipment, practice basic personal hygiene, and avoid direct contact with the waste, the risk for disease transmission is generally low. However, in some developing countries, it is common for poor people to make a living from collection of waste or manual sorting of untreated waste at dumps. Such direct exposure is a high-risk behavior as regards contracting infections from the waste. The risk is further increased if such individuals are in poor physical condition or are already suffering from other diseases. Another exposure problem here is the inhalation of endotoxins.

Indirect exposure to infective agents owing to pathogen pollution of the environment may originate from BW (Figure 1) in the form of leakage or aerosols while handling, storage, or dumping of BW. Pathogen pollution may also follow the use of fertilizers originating from BW. Agricultural use of BW of municipal or industrial origin creates new routes of disease transmission between animals, humans, and the environment and can lead to the contamination of the environmental elements, such as drinking water sources or arable soil. Infections may result directly from the soil or vegetation when domestic or wild animals are grazing on, or

Figure 1 Possible circulation of pathogens between biological waste (BW), animals, humans, and the environment. Squares indicate destiny of BW; ellipses indicate destiny of pathogens.

passing over, the land. Humans may become infected, for example, during recreation activities and exposure to a contaminated environment or water. Pathogens can also be transmitted to humans and animals on dust particles transported by wind, in surface water or groundwater, or in food or feed harvested from the treated land. Water used for irrigation of food crops may be a particularly significant route of disease transmission. Vector animals, for example, insects, birds, and some wild mammalian species, may also spread pathogens to animals and humans, directly from BW produced or through treated BW that has been spread on arable land. Vectors may transmit pathogens themselves directly to a new host by biting or sucking blood, or indirectly by contaminating their food, water reservoirs, or environment. In addition, predators or humans may consume vectors.

The number of microorganisms needed to cause infection in man and animals varies considerably between pathogen species and also depends on the infection route (e.g., oral, inhalation, and through wounds). The susceptibility of an individual also varies depending on age, nutritional status, medical treatment, and other diseases. For some organisms, very low numbers may cause an infection even in healthy individuals, for example, just one embryonated helminth egg may be enough. The proportion of the human population regarded as being immunosuppressed has increased over recent decades. Malnutrition and HIV may be the main reasons for this in the developing world, whereas an ageing population and postoperative medication of transplant patients may be the main causes in the developed world. It is important that the processes involved in handling and treatment of infective waste provide sufficient protection even for these vulnerable groups. In addition, a dose–response relationship exists after exposure to a pathogen. In general, individuals become infected more from a single large dose than from the same quantity in small doses spread over time.

Zoonoses

Many of the actual pathogens in BW are zoonotic agents, which may be transmitted between animals and man. It should be realized that as much as 70% of infectious diseases currently affecting humans are caused by zoonoses and many of the most troublesome pathogens are zoonotic agents. Emerging pathogens may be defined as new, reemerging, or drug-resistant infections with increasing incidence. Of the emerging infectious diseases, 75% are due to zoonoses. Examples can be found among the most serious diseases during recent years, such as BSE, avian influenza, and anthrax. Ingestion of contaminated food or water is the main route of infection in humans for many zoonotic agents, but people can also become infected through inhalation, by direct contact with animals, or from contaminated soil or bathing water.

Salmonella mainly causes gastrointestinal disturbances and is a pathogen well-known all over the world. The genus consists of many serovars; most serovars can colonize the intestine of an extraordinarily broad spectrum of animal species as well as humans. *Salmonella* prevalence in animal production and in the society in general, as well as the strategies to control the infection, varies markedly between countries and regions. In most countries, *Salmonella* is frequently present in many kinds of BW, for example, sewage sludge, manure, and ABP. Verotoxin-producing *Escherichia coli* (VTEC) also causes serious gastrointestinal disturbances and even renal failure in humans. In many developed countries, the infection is endemic among cattle, even though they do not show clinical symptoms. When manure or ABP are not properly sanitized, such products can be an important cause of spread of this infection.

BSE has been extraordinarily important concerning the regulations and procedures for handling ABP, and is also an interesting example of a disease caused by inadequate recycling. Insufficiently heat-treated carcasses of scrapie-infected sheep as well as of the first wave of infected cattle were used as a component of cattle feedstuff. Since the incubation period is several years, the disease had spread widely before the source of the infection became known. BSE among cattle in the United Kingdom has now declined and so has the number of people infected after consumption of infected meat.

Traditional virology has long believed that viruses are quite host-specific, but there are many recent examples of viruses isolated from diseased humans that may have animal origins, for example, hepatitis E virus, and some strains of rotavirus and norovirus. These viruses are all excreted through feces and may therefore be found in certain kinds of BW. It should be borne in mind that viruses are diverse and complex and have the ability to infect different hosts by genetic changes and by the expression of different phenotypic properties.

Zoonotic helminths and protozoa of potential importance in BW include several subspecies of *Ascaris*, *Cryptosporidium*, *Taenia/Cysticercus*, *Giardia*, *Tricinellosis*, and *Toxoplasma*. Most of these agents need only a few organisms to cause infection. *Cryptosporidium* and *Giardia* are a threat in drinking water sources frequently causing epidemics, even in developed countries. Such disease outbreaks often follow flooding or heavy rainfall causing surface runoff or lack of capacity in sewage treatment plants, so sewage is let out untreated to recipient waters.

Human Diseases

Besides all zoonotic *Salmonella*, also some species-specific *Salmonella* serovars such as Typhi and Paratyphi may be of interest in BW sanitation. These cause gastrointestinal symptoms together with other more serious symptoms. Several bacterial species that may be persistent in BW (e.g., *Enterococcus*, *Proteus*, *Streptococcus*, *Pseudomonas*, *Micrococcus*, *Actinomyces*, *Meisneria*, *Bacillus*, and *Klebsiella*) may cause wound infections, sepsis, and even death. Numerous species of intestinal parasites such as *Entamoeba*, *Strongyloides*, *Strongyle*, and *Schistosoma* may also be present in BW. In addition, several virus species can be shed with feces – and infect by the fecal–oral route, for example, norovirus, hepatitis A virus, and rotavirus – and therefore be present in BW.

Animal Diseases

Epizootic diseases can seriously affect animal welfare and cause severe production losses, and therefore epizootic outbreaks are handled very strictly. Eradication commonly involves slaughter of all infected animals and destruction of the carcasses in all infected and infection-suspected herds. This, together with export restrictions on animal products, can have enormous economic consequences for both the farmer and the society.

Classical swine fever is one of the most serious epizootics affecting swine (Figure 2). This togavirus is highly resistant and may remain viable for a long time in the environment or in the gut of people who have consumed infected meat, as well as in BW composed of food scraps. Foot and mouth disease (FMD) is characterized by fever and vesicular eruptions and is caused by an extremely contagious enterovirus affecting cloven-footed animals. Feeding food scraps to swine has caused many outbreaks of the disease, as has handling of ABP. Another animal infection of significance is blackleg caused by *Clostridium chauvoei*, spores of which may persist in soil for many years and infect grazing cattle. Helminths and protozoa of significance to animals are mainly a problem concerning the handling and spreading of manure or if manure is mixed with other kinds of BW.

Figure 2 The virus causing classical swine fever, one of the worst epizootics affecting swine, is highly resistant in the environment as well as in biowaste.

Plant Diseases

Plant pathogens affecting field crops have great economic importance and warrant widespread and frequent use of pesticides. Besides more common ways of infection of the crop plants, pathogens and weed seeds may also be introduced by agricultural use of BW. The inactivation kinetics of plant pathogens in different kinds of hygiene treatment of BW is, in general, the same as that for human and animal pathogens. However, fungal pathogens may develop resting spores, await more advantageous conditions, and survive for many years in, for example, the soil. They are also rather resistant to a number of treatment methods. Some of them may also use many different plant species as hosts. Examples of long-living fungus include white mould (*Scelotinia sclerotiorum*) and club root of crucifers (*Plasmodiophora brassicae*). Furthermore, some plant viruses are hard to be inactivated using heat, for example, tobacco mosaic virus. Plant pathogens are not discussed further in this article.

Antibiotic Resistance

Antibiotic residues/metabolites and antibiotic-resistant bacteria present in sewage sludge, manure, and some other kinds of BW are an emerging public-health concern. The levels and incidence vary according to human and animal medical-care practices and drug-handling routines in the country or region, although antibiotic resistance is a global problem. A favorable environment for resistance development and transmission to other microbes may be present in BW and soil. Antibiotic-resistant bacteria may transmit their resistance genes to better-adapted indigenous bacteria, increasing the resistance reservoir. Handling strategies for BW and more conservative use of antibiotics may help to retain powerful antibiotics in human and veterinary medicine for future generations. Drug resistance is evident in, for example, the treatment of diarrhea-related diseases.

Waste Management Strategies

Produce Less

The volume of waste produced is increasing, but in a society aiming to be sustainable there must be an intention to reduce the burden of waste in both the production and consumption stages. Environmental awareness and education can enhance this trend. An ethical aspect in a long-term perspective concerning the destiny of BW is that it is only reasonable that each generation takes care of its own waste and transforms it into an environmentally harmless or stabilized form. Sorting and reuse or recycling reduce the waste burden, so this is one direction to go for the future (Figure 3). For paper, cardboard, metals, and plastics, recycling is often the producer's responsibility. The at-source management of BW may lower the cost of waste treatment, collection, and transport and possibly generates profits from the by-products or energy produced.

The rendering industry is responsible for the handling of ABP and is an example of a branch where efforts are being made to minimize the production of BW. Humans consume less than one half of a slaughtered animal, so the remaining parts have to be disposed of. Waste material from food processing (animal meat) is frequently heavily laden with microorganisms, the content of pathogens varying widely between different countries or regions. The rendering industry converts huge volumes of ABP from a waste to a resource. ABP is used for many purposes: as feed ingredients for domestic and companion animals; in aquaculture, tanning industry, and technical products; and in heat and energy production. Continuous adaptation to new regulations warranted by biosecurity or environmental reasons, as well as to the market, is essential.

Figure 3 Source separated biowaste aimed for anaerobic digestion. This reduces the waste burden but may be a biosecurity risk if not sufficient hygiene treatment is performed before recycling on arable land.

Get Rid of It

The management strategy for waste in many cases may simply be to get rid of it at the lowest possible cost. Hopefully environmental aspects such as pollution, eutrophication, and greenhouse gas emissions are also considered. Producing renewable energy from waste in the form of heat or methane is one desirable option, but investment needs are generally, but not always, high. Storage of waste, including BW, before such energy recovery may be a problem, although possible to deal with by, for example, baling technology for waste and drying.

Incineration of BW is an attractive solution concerning the biosecurity aspect and also results in a marked reduction in volume. Energy recovery and heat production are possible, but then more advanced treatment systems are generally needed. One of the drawbacks is that gas emissions from treatment facilities may cause air pollution and negative climatic effects. Such gas emissions can be reduced using advanced particle filters. Through the use of ash, minor recycling of plant nutrients may be possible. As for all handling methods of waste, strategies differ between countries or regions or for different kinds of waste. For example, in Japan 100% incineration of combustible waste has been a national waste-management policy. In Sweden, in contrast, recycling of waste before incineration, for example, biodegradation of BW in closed digesters, is proposed. According to the EU legislation for ABP, incineration is compulsory for the highest risk category owing to biosecurity reasons. As long as the temperature during combustion is above 850 °C, even extremely resistant prions are destroyed. Incineration of whole animal carcasses is costly since there is a high energy demand, as well as a demand for special incineration equipment. Production of meat and bone meal is widely practiced, and before the BSE crisis, it was largely used as an ingredient in animal feed. An advantage compared with untreated ABP is that meat and bone meal can be conveniently stored while waiting for incineration. The rendering industry is continuously developing new technologies. In Sweden, a significant proportion of ABP is processed as Biomal, and the energy-demanding processing of the raw material into fat respectively meat- and bone meal is removed. The ABP is crushed and ground and then pumped to a fluidized-bed boiler where it is combusted together with a base fuel such as peat, wood chips, or municipal waste. In the EU, Biomal is regarded as a renewable biofuel not contributing to global warming and can replace fossil fuels for heat and energy production. The heat production from Biomal is about the same as that from incineration of wood chips.

Open dumping of solid waste remains a widely used waste-disposal method around the world. The method is believed to be cheap, but is a generator of ill health. In developed countries, the number and also area of landfills have generally been reduced. The change from open dumping to integrated waste treatment is due to the new and stricter rules for landfilling warranted by environmental and biosecurity reasons, concurrent land use, recycling, and so on. Leachate from landfills, if not collected and treated, can cause environmental problems in surrounding surface-water bodies and groundwater. The European Union has laid down strict requirements for landfills to prevent and reduce such negative effects (1999/31/EC). Examples of individual countries as are making efforts to reduce the use of landfill is Singapore where the long-term goal is towards zero landfill, and in Sweden landfill of organic waste has been prohibited since 2005. This development creates a need for increased investment; as many small local landfills are being shut down. Also longer transport distances of waste to larger facilities may follow.

BW may also be landfilled in biocells, closed compartments from which biogas is recovered at an early stage. Beneficial here is the mitigation of methane (a greenhouse gas) emissions. If degradation variables such as moisture and gas movement are optimized, it is possible to degrade BW within a few years. Such cells may have separate leachate collection, and the fluid may be treated in constructed wetlands. Such treatment may provide the opportunity to digest wastes that are not sufficiently sanitized to be used on agricultural land.

Disposal method for carcasses in many parts of the world, and previously also in Europe, is burial, composting, or feeding to carnivores or birds of prey (domestic or wild). In the United Kingdom, there has been concern about the possible threat to groundwater supplies from buried carcasses of BSE-infected cattle due to the long-lasting nature of the prions, the infective agent. Close to 200 000 cases have been confirmed in cattle, and during the first years of the epizootic, deposit in landfill sites or burial of carcasses was frequent. In the developed parts of the world, well-adapted routines may be present for treating ABP produced at slaughterhouses and also for dealing with sporadic cases of on-farm deaths. However, burial is still used worldwide to get rid of single or numerous carcasses in cases of on-farm deaths, nationwide die-offs, or mass culling of infected animals during outbreaks of epizootic diseases. This method is associated with problems such as contamination of water sources and several biosecurity issues. In Europe, it is used just as one exception to the EU legislation concerning ABP, but sometimes it may be the only way to handle an acute situation. Furthermore, for some extremely contagious diseases such as FMD, transport of infectious carcasses is avoided for biosecurity reasons. At burial, special care should be taken to deposit at sufficient depth (>2 m), in nonporous soil and well separated from groundwater and surface water sources.

Recycle in the Food Production Chain

Treated BW may be a valuable resource as a fertilizer on arable land, in forests, or for other purposes. However, besides the desirable plant nutrients, undesirable pollutants such as infective agents and antibiotic-resistant bacteria are found in BW. Heavy metals, pharmaceutical residues and nonorganic pollutants may also be present but these problems will not be further discussed here.

It is strongly desirable that the handling of BW be viewed in a holistic way with respect to aspects concerning the environment, the economy, and animal and human health. Recycling of BW in the food chain as fertilizer to arable land or as a feedstuff may be beneficial for society and agriculture, as well as the environment. BW transformed from waste to a resource helps to reduce the need for fossil fuel and chemical fertilizers. For organic farming, BW can be very useful as a fertilizer complementary to manure.

In developing countries too, where chemical fertilizers are not regularly available or affordable, use of BW may be highly desirable to increase food and feed yield. It has been observed that in areas where human urine has become a valuable fertilizer, tanks need locks as otherwise the urine is stolen. ABP may be recycled as plant nutrients in the food chain according to EU legislation if pressure-cooked (133 °C for 20 min at 3 bar for risk category 2). Manure also has to be sterilized, although several exceptions exist. Sterilization at high temperature is costly and also diminishes the energy efficiency of treatment, so alternative sanitation methods are highly desirable. Pasteurized (70 °C for 60 min) is enough for risk category 3 but also alternative treatments are permitted if individual member states can validate that such treatment have a hygiene effect equivalent to that of pasteurization. So far, hygiene validation of such new, alternative treatment methods in a scientifically based, generally accepted way is not unquestionably available. According to regulations concerning treatment of ABP and previous opinions from the European Food Safety Authority (EFSA), the pasteurization treatment should reduce the number of relevant pathogenic bacteria by at least 5 log₁₀, the infectious titre of the relevant thermo-resistant viruses by at least 3 log₁₀ whenever they are a relevant hazard, and the number of viable parasitic stages by at least 3 log₁₀ in the given exposure time. So, BW needs to be sufficiently treated before agricultural use. Previous practices, where health drawbacks are now obvious, have included the use of, for example, untreated cow and sheep blood, untreated gut contents from slaughterhouses, or insufficiently treated sewage sludge or other kinds of toilet waste as soil improvers on arable land.

Traditionally, BW including food waste has been fed to domestic animals such as pigs and poultry, while ruminants have been fed with meat and bone meal produced from rendered carcasses and litter from chicken houses. However, this has caused concern since such reuse can spread serious diseases to the animals and further on to humans. The BSE crisis should be still prominent in our minds. Another concern that has prompted the present EU legislation is the ethical (but also biosecurity) aspect that a species should not be forced to eat remains from its own species members. However, use of BW as feed for both companion and certain species of food-producing animals may still be possible, if careful sorting and sanitation treatment are performed first.

Treatment Options for BW to be Recycled to Arable Land

No Best Options Exist

Although it is technically possible to decontaminate BW completely, that is, to sterilize it, before agricultural use, this is an unrealistic proposal, for both practical and economic reasons. Extremely strict regulations will tend to discourage the reuse of BW on arable land, so a balance needs to be maintained between health risks and treatment costs. It must also be borne in mind that the treatment of BW is just one measure, however important, quantifiable, and controllable, against the introduction of infective agents in the environment. Other measures such as restricted spread or use of BW on farmland are discussed further below. Many different treatment options exist for BW to be recycled for agricultural use, and several more are still at the experimental stage. These options include small- or large-scale and low- or high-tech solutions. Universal solutions are unlikely, since a wide variation of situations exists across the world. There is a wide range of opinions and any treatment method may be tested as to its applicability to the local situation. Cost of treatment, possible energy production or consumption, environmental effects, equipment and skill, need for and availability of transport, reduction of smell, possible value and use for the end-product, and so on are factors that should be considered. Traditions (social and religious) and regulations for organic production also may need to be considered. To be successful, suitable treatment methods must combine biosecurity aspects with all these other factors. An efficient hygiene treatment of BW is essential, as agricultural use of BW can inadvertently spread infectious diseases to animals and humans, although opinions differ concerning the risk levels. Advantages of coprocessing BW of municipal, agricultural, or industrial origin include opportunities for the efficient use of large-scale procedures and addition of plant nutrients to agriculture. Some type of risk assessment tool enables treatment methods to be evaluated according to the risk of exposure, dose and type of pathogen, and other measures used.

Possible treatment systems for BW include many different processes based around a biological, physical, or chemical step, some examples of which are given below. Combinations of these methods may also be used. Here the focus is on the sanitation efficiency of the treatment. Acceptable hygiene quality of the end product can be achieved in different ways, among which a temperature/time-dependent method is the most common. The effectiveness of a sanitation treatment may also depend on the pH, the moisture content and the volatile fatty acid content of the treated material, oxygen availability, microbial antagonism, and possible production of for example, antibiotic, exoenzyme, and toxic breakdown products.

Hygiene Assessment of Treatment

The effect of treatment has to be continuously monitored by checking the process, to follow processing parameters such as temperature, pH, treatment time, and composition of the material. Additional information on hygiene level may be obtained by sampling of the end product. However, sampling of nonhomogenous material is complicated, and efficient sample distribution and sampling techniques are essential in obtaining representative samples to perform an accurate hygiene assessment. However, such sampling procedures for large volumes have not yet been standardized. Therefore, it is often easier, and safer, to specify a process rather than the end product. Clear distinctions need to be made between process standards and product standards.

Additional hygiene tests could check directly for the presence of certain pathogens, or comprise a more indirect analysis based on indicator organisms. It is often difficult to quantify pathogens in BW as their incidence is irregular. It should also be borne in mind that in direct analyses, pathogen numbers might be underestimated or undetected in cases where the pathogen is hidden by organic material and/or fat or oil. Another way around is to add well-defined pathogens, for example, teabags of permeable

polyamide containing *Ascaris* eggs, to the process and repeatedly monitor those. However, any kind of covering of microorganisms may cause an overestimation of their potential to persist during the treatment, making them too unreliable as indicators of sanitation effect.

An indicator organism should be easy to detect and common in the material of interest. It should be able to stay alive for an extended period, but should not be able to vigorously multiply. *Enterococcus*, coliforms, thermo-tolerant coliforms, *E. coli*, clostridia spores, *parvovirus*, and *Ascaris* eggs are some commonly used examples. The use of indicators can become complicated since they seldom meet each one of these criteria in the same organism. Indicators can also be added to the material, for example, bacteriophage have been used as virus indicators. The types of checks performed, and the frequency and number of analyses of the end product, vary for different kinds of BW and treatment processes.

The survival of bacteria during different treatment processes is multicausal, and therefore results from different studies are often different and difficult to be compared with one another. In most assessments of hygienic quality, kill-off in the case of bacteria is defined as the level at which the bacteria are no longer detected, most often using conventional culturing techniques on agar plates. However, many bacterial species such as *Salmonella* and *Campylobacter* can enter a viable but nonculturable state and thus prolong survival during periods of nutritional or thermal stress. Animals have been shown to become infected after oral administration of such bacteria. Viable but not culturable bacteria are also able to revert to culturable form if environmental conditions improve. The detection of such bacteria in a substrate or in BW is problematic.

Another consideration is that despite adequate treatment of BW, a risk for multiplication by posttreatment regrowth exists for some bacteria. Growth may be possible in the treated material if stabilization, whereby easily degradable organics are degraded, is not complete. However, neither parasites nor viruses have the capacity for regrowth. Bacterial regrowth may follow when complete elimination of some bacteria is not achieved during treatment, or when reintroduction by, for example, contaminated equipment or vector animals occurs while nutrients are still available. It is therefore essential that treated BW is handled, stored, and transported with great care. Stabilization, biological or chemical, also decreases the risk of methane emission from the end product.

Biological Treatments

Aerobic Digestion

Aerobic digestion, or composting, is a commonly used treatment method for BW of different origins or a mixture of such wastes. Composting may be used for small-scale household kitchen BW to large-scale; centralized windrow composting. It can also be differentiated into open or closed systems, often combined in different steps. Composting may be performed for solid or liquid material. For example, manure, when handled in solid form (>30% dry matter content, feces and bedding material from animal production, with or without excreta in liquid form), makes composting convenient. However, slurry (2–10% dry matter content, feces and bedding material from animal production, mixed with urine and water) may be successfully composted by forced aeration. Another way is to first use liquid–solid separation by mechanical methods and/or polymer flocculation.

Composting relies on thermal inactivation of microorganisms; most of the material must achieve sufficiently high temperature (Figure 4). The compost also needs to be repeatedly turned, 3–5 times for solid material, and/or thoroughly mixed to provide sufficient oxygen and thereby maintain optimal conditions for biodegradation. Addition of structural or bulking material, for example, straw, wood chips, or sawdust may help to absorb moisture and provide carbon and porosity, which will facilitate airflow for proper aeration during composting. An insulation layer above and below the compost or more technically advanced practices, such as preheating of incoming air, can also decrease cold subvolumes within compost heaps. Reactor composting, if the reactor walls are insulated, generally decreases the volume of cold zones compared with open composting. The smaller the volume of cold zones, the more enhanced the degree of sanitization, and therefore fewer turnings/less mixing of the material is needed to reach the sanitization goal. The length of time the compost has to sustain a specific temperature, mostly in the range of 55–65 °C, to become sanitized varies from a few hours to several weeks. According to recommendations given by WHO, sanitization of fecal matter is achieved if >50 °C is maintained for a minimum period of 1 week. At lower temperatures *Ascaris* spp. generally have a high survival rate, whereas at temperatures above 50 °C there is a higher survival rate of dsRNA viruses, for example, Rotavirus.

Figure 4 Composting relies on thermal inactivation of microorganisms; the material needs to be repeatedly turned or thoroughly mixed to provide sufficient oxygen and thereby maintain optimal conditions for biodegradation.

The main environmental concern is that most of the ammonia released during degradation of BW will be lost as an acidifying and eutrophying emission during composting. The high target treatment temperature increases this effect. Controlled reactor-composting offers possibilities to minimize gaseous emissions via condensing or biofilter treatment of the outgoing gas.

Anaerobic Digestion

Anaerobic digestion is today commonly used for biogas production and stabilization of a variety of different BW, including municipal sewage sludge, manure, food waste, and ABP. Large-scale centralized biogas plants may use a mixture of these substrates, although many municipal sewage sludge treatment plants just digest sewage sludge. When practiced at farm level, manure is the main substrate, but cotreatment with, for example, municipal BW may occur. Farm-level anaerobic digesters have been used in, for example, China for centuries, and a growing interest is seen today in some European countries.

Anaerobic digesters are commonly operated at either mesophilic (30–40 °C) or thermophilic (50–60 °C) temperatures. Operations at mesophilic temperatures do not ensure a sanitized material without a preceding sanitization step. During mesophilic anaerobic digestion many unwanted bacteria, as well as some viruses, need more than 2 days for a 1 log₁₀ reduction, according to EFSA. In a survey of anaerobic-digestion plants for sewage sludge in Sweden, *Salmonella* were frequently detected (55%) in treated sludge. Thermophilic digestion (50–58 °C) of BW in a large-scale continuous process sufficiently reduces indicator bacteria and *Salmonella*. Separate pasteurization of substrate in a batchwise step prior to digestion is a reliable sanitization treatment. It also increases the biodegradability of the BW so that more biogas is produced. If a pasteurization step is not used, pathogen reduction has to rely on sanitization in the digestion chamber. Since most large-scale biogas plants use a continuous process and the minimal retention time in the digester may be very short, this is not reliable regarding sanitization. However, unwanted organic pollutants are shown to be more efficiently degraded by mesophilic than by thermophilic digestion.

In Sweden, recontamination of digested residues during postdigestion storage and transport has been observed as a problem. Despite proper sanitization by pasteurization, increased time since pasteurization increases the occurrence and density of unwanted bacteria such as indicators (coliforms and *Enterococcus*) and pathogens (*Salmonella* or VTEC) in digested residues.

Biogas can be used as fuel for kitchen stoves, and therefore hygiene evaluation of biogas from large-scale commercial biogas plants and digesters for sewage sludge has been warranted. The levels of microorganisms in biogas are comparable to the levels in natural gas (10–100 cfu m⁻³). An evaluation of the domestic use of biogas indicates a low risk regarding biosecurity, especially when compared with other risks involved in handling the gas.

Anaerobic digestion is a complex system with environmental benefits, as valuable energy is produced, and the digestate is rich in plant nutrients and is an excellent fertilizer for agriculture. However, depending on the system design, large amounts of methane can escape to the atmosphere during digestion and subsequent storage and handling.

Storage

Simple storage may be classified as a nontreatment concerning pathogen reduction, but some decline in the total number of microorganisms will take place over time. This decline is difficult to predict, and some bacteria may both increase and decrease in numbers in a cyclic manner. As in BW aimed for composting, when the conditions for microbial activity are poor, the temperature will not rise. Some pathogens, for example, VTEC, can persist in liquid manure for several months; the lower the temperature, the longer the survival. Some bacteria (e.g., *Salmonella* and VTEC) can proliferate significantly if conditions are favorable, for example, as regards nutrient availability, so the regular transfer of fresh manure from livestock buildings to slurry tanks may help sustain populations of these pathogens during storage. Levels of indicator organisms such as coliforms and *Enterococcus* vary over time during storage, and pathogen levels are likely to follow a similar pattern. A long storage period without input of fresh material is generally impossible for manure, since storage capacity at farm level is largely determined by the need to store manure until disposed of/used for crop production. Anaerobic lagooning of liquid manure from intensive farming systems is commonly used in certain areas, since it gives rise to low cost and low maintenance-management efforts. Large-scale lagooning may be a potential environmental hazard in cases of faulty design, floods, or earthquakes. Sewage sludge may also be stored for longer or shorter periods of time. Furthermore, long-term storage has a negative impact on the environment if not special caution is taken since emission of the greenhouse gas methane and of ammonia continues throughout the storage period.

Wastewater Treatment

Wastewater treatment is a science on its own, with examples ranging from simple sedimentation in lagoons to high-tech treatment of sewage sludge in biogas reactors. Composting of sludge with or without the addition of other BW and long-term storage are other examples of biological treatment of sludge. As for other BW treated with these methods, the hygiene standard of the treated sludge is in most cases temperature/time-dependent.

Constructed wetlands may be used not only for a third-step cleaning of sewage, but also for treatment of effluents from animal production, landfills, and so on and plants are used for denitrification of such water. If wetland/pond vegetation is harvested and used as a fertilizer in agriculture or for energy production in biogas plants, some degree of recycling of plant nutrients can be achieved. The wetland area may also be intermittently dried and the stored load of plant nutrients used in agriculture, but the

biosecurity risk must then be considered. In addition, constructed wetlands mostly attract vector animals, so the risk of spread of infective agents must also be recognized.

Physical Treatments

Heat Treatment

Heat treatment owing to a temperature rise from microbial activity or by way of external supply of energy is a common and safe hygienic treatment, as long as both the temperature and the treatment time are sufficient. The temperature and the time required depend on the type and strain of organism, the structure of the material, and the moisture content. The higher the temperature, the shorter the time needed for treatment; heat resistance for microorganisms also generally decreases with increasing water activity. Pasteurization at 70 °C for 60 min gives a satisfactory reduction in pathogens for most kinds of BW. However, the reduction of heat-resistant viruses is limited, and spore-forming bacteria are not reduced at all. So if problems are being experienced with a disease caused by these agents, some kind of extended heat treatment or sterilization is necessary. For prions, incineration is a better choice.

Other Physical Techniques

Freezing-thawing is a variant of storage, which has been practiced for sewage sludge in cold climates. The sludge is exposed to repeated freezing-thawing cycles during storage in thin layers. The extent of cell damage caused by the process varies owing to a complex set of factors, and the reducing effect on pathogens from this treatment is variable. The process parameters are difficult to predict, as is the sanitization effect.

Desiccation or air drying to moisture levels <1% has been successful in inactivation of pathogens in municipal BW and in soil. Mortality of dried bacteria is generally enhanced by oxidation processes, since sensitivity to oxygen increases. Drying of animal manure is a widely practiced treatment in certain regions, but the pathogen inactivation effect is not well documented. From laboratory studies, it is known that bacteria dried with their culture medium survive fairly well, whereas suspensions of bacteria from agar surfaces or of washed bacteria generally have only a small percentage of survival. Freeze-drying under controlled conditions is an extensively used method for long-time preservation of bacteria at laboratories.

Chemical Treatments

Chemical sanitization may be achieved by use of, for example, lime or ammonia. Such sanitation requires a closed treatment system, for example, roofed tanks; otherwise, a marked loss of nitrogen by gaseous emission occurs. Lime or other alkaline treatment has been used for, for example, manure and sewage sludge. A pH of >12 for more than 2 h of contact is required. However, alkaline treatment may be effective in reducing most pathogens, although *Ascaris* eggs are rather resistant, if pH 12 is not reached and, according to standard recommendations, maintained for as long as 3 months. In addition to pH and time, factors such as composition of material, storage, and handling conditions are also important. Achieving a homogenous mixture of lime and the material to be treated is not easy, and the handling may cause health problems for workers. The high pH aimed for is also a work hazard. The cost of the treatment may be repaid by an increased value of the fertilizer owing to the added lime.

Ammonia treatment both stabilizes and sanitizes BW. The sanitization effect is achieved at considerably lower pH (9–10) than for regular treatment with bases. The ammonia treatment requires uncharged ammonia for inactivation of microorganisms and a reduction in the viability of *Salmonella* has been noted from 15 m mol l⁻¹ NH₃ at 4 °C. The total ammonia concentration, pH, and temperature regulate the concentration of uncharged ammonia, and therefore it is possible to optimize the treatment. Ammonia is added to, for example, manure or fecal matter either as aqueous ammonia solution or as granulated urea. The environmental and economic cost of ammonia treatment is low, as the ammonia used can be recycled as a fertilizer. An interesting use for ammonia sanitization may be in a mesophilic anaerobic digestion process. If the incoming material is of high protein content, enough ammonia may be released during the anaerobic degradation of proteins for a direct sanitization process to occur. The process needs to be adapted for high ammonia content (8 g l⁻¹) at a pH close to 8, and a high ammonia level can be maintained by restricted feeding of the reactor with a high-protein substrate, for example, pig manure.

Spread and Persistence in the Environment of Infective Agents Originating from BW

Environmental Spread after Pathogen Pollution

Although pathogens occur naturally in the environment and reduction over time will occur, new transmission routes or movement of pathogens to new regions must be avoided. Once pathogen pollution has taken place in the environment, it is impossible to control the spread of the infective agents either in time or in space. Therefore it is of utmost importance to avoid introduction of pathogens to the environment. When BW is to be recycled as a fertilizer, the risk of spread of infections is dependent on a whole set of factors. The initial concentration of the pathogen in BW is of relevance, as is the sanitization efficiency during treatment and the other barriers employed to avoid exposure to animals and humans. Treatment of BW may be absent or inadequate, and other barriers may not be used, leading to problems connected with pathogen pollution.

Other measures complementary to treatment may help decrease the risk of further environmental spread of pathogens and infection of the crops or individuals directly. An example of this may be careful selection of what crop to fertilize, as hygiene-sensitive crops such as vegetables to be consumed raw require a high level of hygiene, whereas for energy crops, a more basic level may be acceptable. The time of the year when BW should be spread on land and the method of application used are other important aspects. Plowing-in or injection reduces pathogen spread and animal exposure, but persistence may be prolonged within soil compared with surface application. An extra safety precaution may be to introduce a restriction time, or quarantine period, before harvest of a crop or grazing of animals. During and after application of BW to land, it is important to avoid its transport to water, which may occur via surface run-off, leakage to groundwater, or flooding (Figure 5). Besides the risk for further spread of pathogens with surface run-off, this may also have negative environmental impacts such as eutrophication and altering of aquatic microenvironments. Aerosols may also result from application of liquid BW, and thus equipment with a low trajectory should be used for spreading to prevent aerosols drifting into adjacent pastures or watercourses. Fine droplets may also be swept by strong winds from the surface of stored liquid BW, with the duration of their ability to hover depending on particle size, relative humidity, and air velocity. Bacteria attached to dust particles are generally better protected against the detrimental influences of solar radiation than those enclosed in aerosol droplets. Depending on the type of soil, strong winds may cause the spread of some pathogens through dust particles. Dust particles may be transported for very long distances, for instance, particles from sandstorms in Africa have been found several hundred kilometers out in the Atlantic sea.

Determining the source of infection for disease outbreak among humans or animals is generally difficult, and the source may not be found. It is usually especially difficult to track the pathogens from an outbreak of a disease – if the pathogen is picked up from the environment – back to the source of the infection.

Vector Animals

Wild animals may acquire a pathogen, and the affected species may act as a disease reservoir for a prolonged time without displaying clinical symptoms. However, wildlife also can be negatively affected, as pathogen pollution may cause infection of immunologically naive wildlife and markedly reduce whole populations. Wildlife and insects may also act as vectors (Figure 6). Vectors are a potential hazard for the spread of pathogens from BW handled at landfill sites, home composting, different treatment facilities, and so on to the surrounding population of humans and domestic- or wild-animal species. BW attracts vectors, and after contact with BW, vectors may carry pathogens on their bodies or in their guts. If BW is sufficiently sanitized and stabilized, the risk of vectors becoming infected is reduced, and the attractiveness of the material for potential vectors is also reduced. The presence of vector animals in places where BW is handled should be reduced to a minimum. However, fencing out wild animals efficiently is associated with obvious problems. Fresh BW needs to be covered instantly to prevent birds and insects feeding on it. The range of vector habitats, migration patterns, and so on may change owing to extreme weather events such as floods, changing ecosystems due to ongoing climate change, deforestation, or other reasons or without obvious reason. Such events may lead to an increase in vector-borne infectious diseases.

Insects may breed in BW, or feed on it. Practically, every enteric pathogen has at some time been isolated in a viable state from insects. Insects may migrate actively, that is, by their own efforts, or be passively transported by wind or by some other kind of vehicle. For example, insects of the species *Psycoidae* have been trapped in a village 13 km away from a dump where they were labelled. This distance is well within the range of active migration.

Figure 5 During and after application of biowaste to land, it is important to avoid its transport to water, which may occur via surfaces run-off or flooding.

Figure 6 Biowaste attracts vectors and insects may carry pathogens on or within their bodies. Vectors are a potential hazard for the spread of pathogens to humans and animals.

Birds such as gulls (*Laridae*) and crows (*Corvidae*) and birds of prey such as owls, hawks, and buzzards may feed on BW and/or visit landfill sites. Eagle owls (*Bubo bubo*), in particular, are often seen on landfill sites, as they feed on small rodents. Not surprisingly, *Salmonella* is more often isolated from gulls in areas with lower hygiene standards than those in areas with better standards. When gulls use landfill sites to feed, they tend to visit the site during the daytime and thereafter stay in the surrounding area. Since birds have a daily need for water, bird droppings may contaminate water supplies in the surrounding environment. However, birds should be perceived not only as a local problem for the handling and treatment sites of BW and their immediate environment; long-distance transmission of pathogens with birds can also occur, especially during the winter season when many birds migrate to other regions or countries.

Some mammalian species such as red fox (*Vulpes vulpes*), hare (*Lepus*), roedeer (*Capreolus capreolus*) and, not the least, different species of rodents may be more or less permanent visitors on, for example, landfill sites. Wild animals acting as a reservoir for contagious diseases is a well-recognized problem in many parts of the world. For example, wild boars (*Sus scrofa*) have been found to be infected with classical swine fever in Eastern Europe. Wild boars infected from contact with BW may then transmit the infection to domestic swine, causing an *epizootie*.

Persistence

The ability of an organism to persist in the environment is critical to its transmissibility, as the opportunity to come into contact with a susceptible host increases. Agents that can infect many different species are more likely to find a suitable host compared with species-specific agents. Both the survival and growth potential of pathogens in the environment vary considerably between different species and subtypes of microorganisms. Parasites, spore-forming bacteria, prions, and some types of viruses (e.g., Parvo) generally persist for the longest periods of time. Eggs of some helminths, especially *Ascaris*, are very persistent and have been shown to be still viable even after 15 years. Helminths typically require time in the environment to develop into an infectious stage and may pass through one or more intermediate hosts, for example, *Schistosoma*. Spore-forming bacteria such as *Bacillus* and *Clostridia* species are extremely persistent in the environment and may stay viable for decades buried in dry soil, where microbial activity is minimal. Several examples of unexpected infection of cattle have been reported after digging in places where unknown anthrax-infected carcasses had been buried decades previously. In the surface layer of soil, in competition with other organisms, anthrax spores may disappear within a few years. In Germany, it was noted in connection with World War I that losses of cattle to anthrax on pastures flooded by water from rivers into which tanneries had drained their spore-contaminated sewage drastically diminished. Cattle losses increased subsequently once contaminated hides were again imported after the war. Other interesting observations concerning the potential of *Bacillus anthracis* to multiply in soil have been made during periods of major climatic and ecological changes in which the soil microenvironment is altered in such a way that spores start to germinate and multiply. Thawing of permafrost in East Siberia is today causing awareness of increasing numbers of anthrax cases. In the beginning of 1900 massive outbreaks of the disease caused 1.5 million dead deer, most of them buried in the permafrost. Permafrost warming may lead to the release of viable anthrax spores.

Other bacteria may also survive in the environment for periods over 1 year, if temperature, humidity, type of soil, and so on are favorable. Different soil types affect microbial survival in different ways owing to their texture, pore space, surface activity, moisture-holding characteristics, presence of essential nutrients, types of autochthonous microorganisms, and so on. Some pathogenic bacteria such as *Salmonella* and VTEC can multiply in favorable circumstances, such as after rainfall. To increase persistence, different *Salmonella* serovars adjust themselves to the surrounding circumstances in different ways. For many pathogens such as new viral pathogens, there is little information available about their persistence in the environment or their removal during treatment of BW. Prions may most likely persist for a very long time, although there is no evidence that BSE infection in animals occurs directly from the environment. For other transmissible spongiform encephalopathies agents such as scrapie in sheep and chronic wasting diseases in cervids, their persistence in the soil is thought to play an important role in animal-to-animal transmission. Extremely hard efforts are being practiced in the western world to avoid environmental pollution with prions.

In general, the survival rate of microorganisms is lower in terrestrial environments compared with aquatic environments, mainly due to higher microbial activity and antagonism in soil. Natural inactivation factors on plant surfaces, in soil, and in feed and foodstuff also vary considerably due to climate, season, vegetation, soil type, and so on. Physicochemical factors such as sunlight, temperature, desiccation, dilution and pH, and biological factors such as antimicrobials produced by *Microbiota*, predation, bacteriophage, and nutrient competition reduce pathogenic microorganisms over time. However, this type of reduction in pathogens is unreliable and should not be overestimated. In general, survival is prolonged in cold climates, a fact that must be taken into consideration if a quarantine period is established as a safety precaution/barrier between spread of BW and crop harvest/grazing. Ongoing climate change may change the possibilities for persistence of some pathogens in the environment. For example, parasite survival may be favored if winters become warmer and humidity increases, but negative effects may follow if the protective layer of snow is sparse. Vegetation may also provide a protective environment and enhance pathogen survival.

Conclusions

Widespread efforts are being made to reduce the burden of waste on the society, but further improvements are needed. Management strategies include producing less waste, reusing and recycling, and simply disposing of waste by dumping or incineration. Recycling of BW is desirable for several reasons, but it must be done in such a way that it does not constitute a risk to human and/or animal

health or to the environment. BW must always be assumed to contain infectious agents of animal, human, or plant origin. More or less severe infections are found, including epidemic, epizootic, and zoonotic infections of significance. Recycling of BW in agriculture enables reuse of plant nutrients and reduces the need for artificial fertilizers and nonrenewable energy. Sufficient hygiene treatment before the spread of BW as a fertilizer is essential to avoid ecosystem contamination with pathogens. Additional barriers such as a restriction period between spread of BW and harvest/grazing may also help. Pathogens can persist for long time in the environment and be transported for long distances. Vector animals and water are central to the spread of many infective agents. In addition, today's intensive travel and trade make the vulnerability to infectious diseases a universal problem.

Introduction

The Biology of *Photorhabdus* and *Xenorhabdus*

Bacteria, nematodes, and insects

Photorhabdus and *Xenorhabdus* bacteria live in association with nematodes from the families Heterorhabditidae and Steinernematidae, respectively (Forst et al., 1997). Both genera bacteria are members of the Enterobacteriaceae, and are found as symbionts within the guts of the infective juvenile nematodes (ffrench-Constant et al., 2003). These infective juvenile nematodes seek out and invade insects, whereupon the bacteria are released from the mouth of the nematode directly into the insect blood system or hemocoel (Forst et al., 1997). The bacteria then multiply rapidly within the insect, apparently unaffected by the insect immune system (Silva et al., 2002). In the case of *Photorhabdus*, the bacteria first colonize the gut and grow rapidly in the hemocoel only, later colonizing all the other insect tissues (Silva et al., 2002). The nematodes also multiply within the insect cadaver, feeding off both the bacteria and the degraded insect tissues (Forst et al., 1997). Finally, a new generation of infective juvenile nematodes reacquires the bacteria and leaves the insect in search of new hosts.

During the course of this infection process the insect dies and the bacteria are inferred to secrete a range of toxins capable of killing the insect or attacking specific tissues (ffrench-Constant et al., 2003). For the purposes of this article, it is important to note that during this process the bacteria lie within the hemocoel of the insect or within the insect tissues. Therefore, any toxin action on the gut in vivo is likely to be from the hemocoel side of the gut. The existence of toxins acting from the lumen side of the gut is therefore, unexpected from the biology of the organism (Bowen et al., 1998). In this respect, this article is divided into sections on the orally active Toxin complexes (Tc's) and on the injectably active Makes caterpillars floppy (Mcf) toxins.

Bacterial nomenclature

As this article involves the description of toxins from a wide range of *Photorhabdus* and *Xenorhabdus* strains, some description of current bacterial taxonomy is necessary to clarify subsequent discussion. The genus *Xenorhabdus* contains a number of species including *Xenorhabdus nematophilus*, *Xenorhabdus beddingii*, *Xenorhabdus bovienii*, and *Xenorhabdus poinarii* (Forst et al., 1997). The taxonomy of the genus *Photorhabdus*, however, is more complicated and has recently been revised. In this revision (Fischer-Le Saux et al., 1999), the genus was recently split into three species, *Photorhabdus luminescens*, *Photorhabdus temperata*, and *Photorhabdus asymbiotica*. Two of these genera have also been subdivided into new subspecies. Thus, the *P. luminescens* group has three subspecies, *luminescens*, *akhurstii*, and *laumondii*, and the *P. temperata* group has one subspecies, *temperata*. The third species group, *P. asymbiotica*, which consists of isolates from human wounds recovered in the apparent absence of a nematode vector (Gerrard et al., 2003), has not yet been subdivided. Most of the genetic analyses have been performed on a limited number of strains: *P. luminescens* subsp. *akhurstii* strain W14, *P. luminescens* subsp. *laumondii* strain TT01, and *P. temperata* strains K122 and NC1. For brevity these strains will be referred to as *Photorhabdus* strains W14, TT01, K122, or NC1, or simply W14, TT01, K122, and NC1, except where reference to their different specific designation is relevant to the discussion.

The Need for Alternatives to *Bacillus thuringiensis*

To date, the majority of transgenes deployed in insect resistant crops are *Cry* genes from *Bacillus thuringiensis* or "Bt." Despite the diversity of *Cry* genes cloned from *B. thuringiensis*, only a few *Cry* proteins are toxic toward specific pests. This observation has led to concerns about the development of resistance to specific *Cry* toxins and over the subsequent management of cross-resistance to other toxins occupying the same or similar binding sites (Ives, 1996; McGaughey et al., 1998). These concerns are increasing as specific cases of laboratory-developed Bt resistance are documented in pest insects (McGaughey, 1985; Gahan et al., 2001). *B. thuringiensis* has also proved to be a useful source of other non-*Cry* genes such as the vegetative insecticidal proteins or "Vips" (Estruch et al., 1996; Yu et al., 1997); however, this organism clearly has a limited capacity to produce further toxins. The work described here on the isolation and characterization of insecticidal toxins from *Photorhabdus* and *Xenorhabdus* has been performed partly in the search for alternative novel insecticidal proteins for insect control.

[☆]Change History: October 2016. This article first appeared in Comprehensive Molecular Insect Science, edited by Lawrence I. Gilbert, Kostas Iatrou, and Sarjeet S. Gill, Elsevier B.V., 2005, pp. 239–253 and was reprinted in Insect Control, edited by Lawrence I. Gilbert and Sarjeet S. Gill, Elsevier, London, 2010, pp. 313–327.

This article is an update of R.H. ffrench-Constant, N. Waterfield, P. Daborn, 5.8 – Insecticidal Toxins From *Photorhabdus* and *Xenorhabdus*, *Comprehensive Molecular Insect Science*, edited by Lawrence I. Gilbert, Elsevier, 2005.

The Toxin Complexes

Discovery of the Toxin Complexes

Purification and cloning of *Photorhabdus* toxins

Despite the fact that *Photorhabdus* is released directly into the insect hemocoel by its nematode host, the culture supernatant of *Photorhabdus* strain W14 shows unexpected oral toxicity to the lepidopteran model *Manduca sexta* (Bowen and Ensign, 1998). A toxic high molecular weight protein fraction was purified from the W14 supernatant by sequential ultrafiltration, dimethyl aminoethyl (DEAE) anion-exchange chromatography, and gel filtration (Bowen and Ensign, 1998). As a final purification step, high-performance liquid chromatography (HPLC) anion-exchange chromatography was used to separate four peaks or "Toxin complexes" A, B, C, and D (Bowen et al., 1998). Purified Toxin complex A (Tca) has a median lethal dose of 875 ng cm⁻² of diet against *M. sexta*, and is therefore as active as some Bt Cry proteins (Bowen et al., 1998). The histopathology of orally ingested Tca shows the primary site of action to be the midgut, where cells of the midgut epithelium produce blebs as the epithelium itself disintegrates (Blackburn et al., 1998). Interestingly, injection of purified Tca also results in destruction of the midgut with a similar histopathology, suggesting that Tca can act on the gut from either the lumen or the hemocoel (Blackburn et al., 1998).

Each of the HPLC purified complexes migrates as a single or double species on a native gel but resolves into numerous different polypeptides on a denaturing sodium dodecylsulfate (SDS) gel (Bowen et al., 1998). The *toxin complex* (*tc*) encoding genes were cloned by raising both monoclonal and polyclonal antisera against the purified complexes and using these to screen an expression library. Each of the four complexes Tca, Tcb, Tcc, and Tcd is encoded by four independent loci *tca*, *tcb*, *tcc*, and *tcd* (Bowen et al., 1998). Each of these loci consists of an operon with successive open reading frames, for example, *tcaA*, *tcaB*, *tcaC*, and *tcaZ* (Fig. 1). These open reading frames encode the different polypeptides that can be resolved from the native complexes as confirmed by N-terminal sequencing of the individual polypeptides resolved on an SDS gel (Bowen et al., 1998). Genetic knockout of each of the *tca*, *tcb*, *tcc*, and *tcd* loci in turn showed that both *tca* and *tcd* contribute to oral toxicity to *M. sexta* and that removal of both these loci in the same strain renders the double mutant nontoxic (Bowen et al., 1998).

Similar independent purification approaches to the supernatant of strain W14 identified two high molecular weight complexes, confusingly termed "toxin A" and "toxin B," with oral activity to the coleopteran *Diabrotica undecimpunctata howardi* (Guo et al., 1999). These two toxins correspond to the species TcdA and TcbA, respectively, therefore confirming that both Tcd and Tcb also have activity against Coleoptera. The native molecular weights of TcdA and TcbA were estimated at 860 kDa, leading to the suggestion that they are tetramers of the 208 kDa species observed on an SDS gel (Guo et al., 1999). These species can also be proteolytically cleaved by proteases found in the culture supernatant and an increase in insecticidal activity associated with the cleaved form of the toxin was reported (Guo et al., 1999). However, the nature of the protease responsible and the relevance of the cleavage in the biological activity of the toxins remain obscure.

Cloning of *Xenorhabdus* toxins

Supernatants of some *Xenorhabdus* strains also show oral toxicity to insects. Oral insecticidal activity against another lepidopteran, *Pieris brassicae*, was used to identify *tc* gene homologs from *X. nematophilus* PMF1296 (Morgan et al., 2001). In this study, a cosmid

Fig. 1 The *toxin complex a* (*tca*) locus from three different *Photorhabdus* strains highlighting the three different color-coded elements *tcaAB*, *tcaC*, and *tccC* (see key). Note that this locus is only complete in strain W14 (in which it confers oral toxicity) and that in TT01 the locus is deleted from the equivalent location in the genome and found as a partially complete copy elsewhere (see text for discussion).

library was made in *Escherichia coli* and individual cosmids were screened for oral activity. Two overlapping cosmids with oral activity were recovered and one of these was completely sequenced. Transposon mutagenesis of the cosmids was then carried out to discover which open reading frames were involved in oral toxicity (Morgan et al., 2001). The genes encoding insecticidal activity were termed *Xenorhabdus* protein toxins (*xpt*) and insertions within the large gene *xptA1* were associated with a loss of oral activity (Morgan et al., 2001). The predicted amino acid sequences of the *xpt* genes show high similarity to the *tc* genes of *Photorhabdus* and their closest homologs have been indicated in a revised map of the open reading frames found in the cosmid (Fig. 2). The orally toxic *Xenorhabdus* cosmid therefore contains two *tcdA* homologs transcribed in opposite directions (*xptA1* and *xptA2*) with *tcaC* (*xptC1*) and *tccC* (*xptB1*) homologs between them. Expression of one *tcdA*-like gene (*xptA1*) alone in *E. coli* was sufficient to reproduce oral activity in *E. coli* (Morgan et al., 2001). This data suggests that the two different genera of nematode symbionts use similar toxin complex-like genes.

Genomic organization of *Photorhabdus tc* genes

Extended sequencing of the *tcd* locus in strain W14 revealed that clusters of *tcdA*-like genes were present in the *Photorhabdus* W14 genome (Fig. 3). Further, these multiple *tcdA* and *tcdB*-like genes are inserted next to an AspV tRNA in a potential pathogenicity island (Waterfield et al., 2002). This island is a region of DNA inserted in putative "core" sequence, i.e., sequence similar to core sequences in *E. coli* and *Yersinia pestis*. The island contains multiple copies of *tccC*-like sequences, which may promote recombination, and also enteric repetitive intergenic consensus (ERIC) sequences (Waterfield et al., 2002). The region also contains numerous directly duplicated open reading frames and a fragment of a *tcdA*-like gene, suggesting that it may be prone to rearrangement. Finally, a comparison of pathogenicity islands or phage inserted at the Asp tRNA in other related bacteria shows similar genomic islands carrying other toxin genes and *rhs* elements in place of *tccC*-like elements (Fig. 4). All these factors combine to support the concept that the *tcd*-island is a pathogenicity island. Moreover it is interesting to note that this island is adjacent to a gene *ngrA* implicated in nematode symbiosis (Ciche et al., 2001). Thus regions containing insect pathogenicity genes and nematode symbiosis factors may be linked in the W14 genome.

Homologs in Other Bacteria

Homologs of *tc* genes have now been found in other bacteria, both those pathogenic to insects and also bacteria with no obvious insect association (Waterfield et al., 2001b). Gene homologs are found in *Serratia entomophila*, a free-living bacterium causing "amber disease" in the New Zealand grass grub, *Costelytra zealandica* (Hurst et al., 2000). Larval disease symptoms after oral ingestion of *S. entomophila* include cessation of feeding, clearance of the gut, amber coloration, and eventual death. In *S. entomophila*, the disease determinants are encoded on a 115 kb plasmid designated pADAP, for amber disease-associated plasmid (Glare et al., 1993). Introduction of pADAP into *E. coli* is sufficient to confer oral toxicity on the whole bacteria (Hurst et al., 2000). The genes encoding the amber disease toxins were mapped to a 23 kb fragment of pADAP and then identified by insertional mutagenesis. The three disease-associated genes were termed *S. entomophila* pathogenicity (*sep*) genes (Hurst et al., 2000). These predicted products of

Fig. 2 Comparison of *tc*-like loci in entomopathogenic bacteria. *Yersinia pestis* is vectored by the flea and carries a *tca*-like locus, complete in biovar KIM but with *tcaB1* disrupted in biovar CO92. *Serratia entomophila* is a free-living bacteria that infects grass grubs. In this species the *tc*-homologous *sepABC* is carried on a conjugative plasmid required for insect pathogenicity. In *Xenorhabdus nematophilus*, vectored by a nematode, *tc*-homologous genes lie on a cosmid clone recovered on the basis of oral toxicity to caterpillars. Note again that the color coding indicates homology with the three central *tcaAB*, *tcaC*, and *tccC*-like elements (see key).

Fig. 3 The toxin complex *d* (*tcd*) locus from four different *Photobacterium* strains highlighting the three different color-coded *tcaAB/tcdA*, *tcaC/tcdB*, and *tccC*-like elements (see key). Comparison of the four loci shows a conserved core (boxed in gray) and then localized deletions within and between the different *tcd* homologs (see text). Note that the *tcd* locus from W14 can confer oral toxicity on recombinant *Escherichia coli*.

Fig. 4 Comparison of *Photobacterium* W14 *tcd* pathogenicity island with pathogenicity islands also inserted at the Asp tRNA in other related bacteria. The “core” sequence flanking the inserted island is shown. Note the common elements of the pathogenicity islands sharing insertion near a tRNA, toxin genes and mobile elements (see key).

these genes show high similarity to those of the *tc* genes and are again clearly homologs. Thus *sepA* is *tcd*-like, *sepB* is *tcaC*-like, and *sepC* is a *tccC*-like gene (Fig. 2). The finding of *tc*-like genes in a bacterium with no known association with a nematode shows that this class of genes is not specific to nematode symbionts. Further, the presence of the *sep* genes on a plasmid supports the concept, derived from the *tcd* island of *Photobacterium* W14 (Waterfield et al., 2002; ffrench-Constant et al., 2003), that the *tc* genes can be found on unstable or mobile stretches of DNA.

More recently, *tca*-like genes have also been discovered in both the sequenced genomes of *Y. pestis* (Parkhill et al. 2001; Deng et al., 2002), the causative agent of bubonic plague (Perry and Fetherston, 1997). Although highly pathogenic to man, *Y. pestis* is vectored by fleas and is therefore insect associated for part of its life cycle. Following uptake of an infected blood meal the

midgut of the flea becomes “blocked,” a process facilitating transmission of the infected blood to the next mammalian host (Hinnebusch et al., 1996). The hypothesis that the *tca* homolog in *Y. pestis* may be involved in midgut blockage was investigated by making a knockout mutant of the gene and examining its effect on blood feeding in the flea. However, no direct effect of the *tca* mutant on midgut blockage was seen (French-Constant, Perry, and Hinnebusch, unpublished data). The functional role of this gene in *Y. pestis* therefore remains unknown. The observation that one of the *tca* open reading frames is apparently disrupted in strain CO92 led Parkhill et al. (2001) to suggest the alternative hypothesis, that loss of *tca* function may actually be required for persistence of *Y. pestis* in the flea gut. Further, the presence of an intact *tca* homolog in the recent putative ancestor of *Y. pestis*, *Y. pseudotuberculosis* (S. Hinchcliffe, personal communication), supports the concept that *tca* function may have recently been lost.

Gene homologs can also be detected in the genomes of bacteria with no currently known associations with insects. In *Pseudomonas syringae* pv tomato, there is a locus with *tcaC*, *tccB*, and *tccC* homologs (Fig. 5). Although this bacterium has no known association with insects, as a plant pathogen it may have an undescribed insect vector. Finally, and most recently, *tc* homologs have been found in the genome of *Fibrobacter succinogenes*, a commensal of ruminants with no obvious insect association. This growing range of noninsect associated bacteria with *tc* gene homologs may suggest that this class of genes is widely found in Gram-negative bacteria and that insect toxicity has been acquired in only a limited subset of *tc* gene homologs. The inferred ancestral function of *tc* homologs, however, remains obscure.

Molecular Biology of the Toxin Complex Genes

Toxin complex gene organization

The previous survey of *tc* gene homologs found in a range of bacteria leaves us with a confusing array of gene names and homologies. However, several aspects of the genomic organization of these genes in different species begin to indicate which may be the minimal functional units of insect toxicity. First, a color-coded comparison of *tc* loci in different bacteria shows that the different loci are mainly variations on a simple theme of three basic gene types: (1) *tcdA*-like genes, (2) *tcaC*-like genes, and (3) *tccC*-like genes (Figs. 1–3). Second, where isolated pieces of DNA can confer oral toxicity, such as the pADAP plasmid of *S. entomophila* (Hurst et al., 2000) and the cosmids isolated from *X. nematophilus* (Morgan et al., 2001), only these same three gene types are required for full toxicity. This effectively gives us a working hypothesis for attempts to recombinantly express *Photorhabdus* toxins, i.e., that combinations of these three types of genes are required for the expression of full oral toxicity.

Expression and structure of *Photorhabdus* toxins

Following the demonstration that knockout of either *tca* or *tcd* in *Photorhabdus* W14 decreases oral toxicity and in the absence of orally toxic cosmids carrying these loci, it was required to define the minimal components necessary for full oral toxicity in *E. coli*. In these experiments plasmids were inserted into *E. coli* carrying either (1) *tcdA* alone, (2) *tcdA* and *tcdB*, or (3) *tcdA*, *tcdB*, and *tccC* together. Only the plasmid carrying all three genes confers oral toxicity when expressed in *E. coli* and toxicity is increased by induction of the culture with mitomycin, suggesting that Tc production may be related to stress induced by this phage-inducing agent. Electron microscopy of high molecular weight particle preparations of the recombinant protein showed the Tc complexes to be “ball and stick” shaped particles of 25 nm in length (Waterfield et al., 2001a). Further, despite the fact that the presence of *tccC* is necessary for full oral toxicity, the particles themselves can be made by *tcdA* and *tcdB* alone. This suggests that TccC plays a critical role in the activation or export of the complex but does not change the physical structure of the *tcdAB*-derived structure.

Finally, despite the unexpected oral activity of the Tc toxins, how does *Photorhabdus* itself employ these toxins in a normal infection? Immunocytochemistry using an anti-TcaC antibody in insects infected with *Photorhabdus* W14 shows that TcaC is produced during infection of the insect midgut (Silva et al., 2002). During infection, the bacteria occupy specific grooves in the midgut,

Fig. 5 Comparison of *tc*-like loci in bacteria with no known insect association showing that *tc*-like genes can also be found in plant pathogens with no known insect vector like *Pseudomonas syringae* and even ruminal commensals like *Fibrobacter succinogenes* (see text for discussion).

penetrating under the sheathing extracellular matrix to lie directly underneath the midgut epithelium. Within this sheltered niche the bacteria produce Tca, much of which appears to be associated with the bacterial outer membrane (Silva et al., 2002). In this fashion the gut active toxin can be delivered in extreme proximity to the midgut epithelium itself.

The Makes Caterpillars Floppy Toxins

Discovery of Makes Caterpillars Floppy

Cloning of *mcf1*

Although the Tc's account for the oral toxicity of some *Photorhabdus* supernatants, the nature of the toxins used by the bacteria growing within the hemocoel to actually kill the insect host remain unclear. To investigate potentially injectably active toxins individual cosmids were employed but this time injecting *E. coli* cultures carrying each cosmid individually into *M. sexta* caterpillars (Daborn et al., 2002). By injecting 2×10^7 cells per culture, 300 clones were injected and a single cosmid that resulted in death of the insect was recovered. As well as killing the insect, the cosmid also induced a rapid loss of body turgor, termed the "floppy" phenotype (Daborn et al., 2002). The cosmid was mutagenized with 126 single transposons to look for insertions showing the loss of either phenotype. The same insertions were also used as entry points to sequence the complete cosmid and identify open reading frames. Out of 126 insertions, 39 negated both phenotypes and all of these lay within a single 8.8 kb gene. This gene also caused both death and loss of body turgor when *E. coli* carrying this gene alone were injected into caterpillars. Therefore, this open reading frame was termed the *makes caterpillars floppy* gene or *mcf*. This open reading frame predicts a high molecular weight protein of 324 kDa. However, the predicted protein shows little homology to other proteins in the databases. Three regions of limited homology are present (Fig. 6). First, the C-terminus shows similarity to a repeated sequence found in RTX-like toxins (Schaller et al., 1999) potentially involved in toxin secretion. Second, part of the central domain is similar to the translocation domain from toxin B of *Clostridium difficile* (Hofmann et al., 1997). Finally, a region in the N-terminus matches the consensus sequence for a Bcl-2 homology domain 3 (BH3) domain. Vertebrate proteins involved in apoptosis that contain only this domain are proapoptotic (Budd, 2001), leading to the working hypothesis that Mcf itself may also promote apoptosis. Interestingly, if proved, this would be the first BH3 domain found outside of eukaryotes.

The observation that *E. coli* expressing Mcf alone can survive in the presence of the insect immune system is unexpected. Normally, *E. coli* carrying a pUC18 plasmid are cleared from the insect, presumably via the action of both antibacterial peptides and the insect phagocytes or hemocytes. In contrast, *E. coli* carrying pUC18-*mcf* and a second green fluorescent protein (GFP) expressing plasmid persist longer in the hemolymph. Dissection of infected animals shows that the Mcf and GFP expressing bacteria can colonize tissues in the insect and that the hemocytes fail to encapsulate the bacteria in melanin. Therefore, it was speculated that this failure to encapsulate Mcf expressing bacteria was due to hemocytes, dying via Mcf induced apoptosis. To investigate whether Mcf can promote apoptosis in hemocytes, the hemocyte monolayers were exposed to recombinant Mcf. The results show that exposed hemocytes, disintegrate rapidly, within 6 h, by producing numerous characteristic blebs. The residual actin cytoskeleton also shows a characteristic punctate pattern of staining. This proapoptotic effect on hemocytes helps to explain how recombinant *E. coli* can persist in the insect but fails to explain how the insects lose body turgor and die.

To examine the cause of the floppy phenotype, the histopathology of insects infected with *E. coli* expressing Mcf was investigated. Given that both the Malpighian tubules and the midgut are responsible for osmoregulation, destruction of either of these organs

Fig. 6 The Makes caterpillars floppy (Mcf) toxins 1 and 2 compared to toxins from *Pseudomonas fluorescens* (Pfl 4315) and *Clostridium* (confusingly termed TcaB but not a Tc toxin). Both Mcf1 and Mcf2 have domains in their N-termini putatively associated with apoptosis, namely a BH3 and HRMA-like domain, respectively. Two regions of similarity within this class of toxins are highlighted. First a transmembrane domain found in the *Clostridium* toxin and second an RTX-like export domain found in the C-terminus of both Mcf proteins.

Fig. 7 Comparison of *mcf1* containing loci from four different *Photorhabdus* strains. Note that *mcf1* lies alongside a Phe tRNA in both W14 and TT01; however, W14 also carries *palBA*. In the other two strains sequenced, K122 and ATCC43949, *mcf1* appears to occupy different genomic locations suggesting that the toxin is mobile within the *Photorhabdus* genome.

Fig. 8 Comparison of *Photorhabdus* W14 *mcf1* pathogenicity island with pathogenicity islands also inserted at the Phe tRNA in related bacteria. The “core” sequence flanking the inserted island is shown. Note the common elements of the pathogenicity islands sharing insertion near a tRNA, toxin genes and mobile elements (see key). Note also the similarities in genomic organization with the *tcd* island in Fig. 4.

could result in a rapid loss of body turgor. Sections of infected caterpillars showed that the Malpighian tubules were intact at the time of death but cells of the midgut epithelium were severely affected as early as 12 h post injection. Both goblet and columnar cells shed circular blebs, often including the nucleus, into the midgut lumen. Nuclei within the dying cells appear pycnotic and stain terminal deoxynucleotidyl transferase-mediated dUTP end labeling (TUNEL) positive, suggesting that they are apoptotic. These observations are consistent with Mcf having a proapoptotic function and with its primary site of action being the insect midgut. However, some caution is necessary in interpreting these results as insects ingesting *B. thuringiensis* Cry of Vip toxins also show a similar histopathology of the midgut. More specific experiments to show that Mcf is proapoptotic are therefore needed.

Comparison of the genomic location of *mcf1*-like genes between *Photorhabdus* strains confirms two important points (Fig. 7). First, *mcf1*-like genes appear to be present in all strains of *Photorhabdus*, as would be expected if Mcf1 is a dominant toxin. Second, like the *tc* toxins, the location of *mcf1* differs between genomes and is often associated with either a Phe tRNA or integrase genes. In fact in strain TT01, *mcf1* is adjacent to a Phe tRNA on one side and the downstream of the *tccC* locus, suggesting that in this case both a *tc* and *mcf* locus may be found together on the same pathogenicity island. Finally, comparison of the relative genomic location of the island containing *mcf1* in *Photorhabdus* strain W14 with other islands inserted at the Phe tRNA in related bacteria again show a similar pattern with other toxins being inserted alongside integrase genes or integrase gene fragments (Fig. 8).

This confirms that *Photorhabdus*, like related enteric bacteria, carries a range of toxin encoding pathogenicity islands inserted at tRNA genes.

Cloning of *mcf2* homologs

Sample sequencing of the *P. luminescens* W14 genome revealed the presence of a second *mcf*-like open reading frame termed *mcf2*. The predicted Mcf2 protein is similar to Mcf1 (Fig. 6) but is significantly shorter at the N-terminus. Further, rather than carrying BH3-like domain, part of the N-terminus shows similarity to HrmA from *Pseudomonas syringae* pv. *syringae* (Fig. 6). The *hrmA* gene encodes a protein that has an avirulence (*avr*) phenotype in plants, travels a type III (Hrp) secretion system, and also elicits cell death when transiently expressed directly in tobacco cells. This suggests that HrmA is a type III delivered effector that can cause apoptosis in plant cells. The similarity of HrmA with part of Mcf2 suggests that Mcf2 may also be involved in inducing apoptosis but via a different mechanism than Mcf1. In this case, it is interesting to note how a type III effector protein such as HrmA, which is normally delivered directly into the cell, has become fused within the N-terminus of Mcf2 to be delivered within the high molecular weight protein via an undescribed mechanism. Comparisons of available sequence data from different *Photorhabdus* strains suggests that copies of *mcf1* are always present, suggesting it may be the dominant insect killing toxin (Fig. 7). However, we remain uncertain about the distribution of *mcf2* and although this toxin is present in W14 and TT01, this gene is not present in currently available sequence from the *P. asymbiotica* isolate being sequenced at the Sanger Center. It is therefore not clear if *mcf2* is a required toxin present in all *Photorhabdus* strains like *mcf1* or if it is only present in a subset of strains.

Toxin Genomics

Microarray Analysis

The widespread distribution of the *tc* genes between different bacteria raises interesting questions as to their origins and transmission. To examine these questions in *Photorhabdus* strains the simple question should be answered: is oral toxicity monophyletic? In other words, do all *Photorhabdus* strains with orally toxic supernatants belong to the same taxonomic group? To address this question, two parallel approaches were used. First, phylogenetic analysis of orally toxic and nonorally toxic strains using 16S DNA sequences was carried out. Second, hybridized genomic DNA from each strain to a microarray carrying 96 putative virulence factor genes from the orally toxic *Photorhabdus* strain W14 was done to investigate the minimal subset of *tc* genes required for oral toxicity.

The phylogenetic analysis showed that the six orally toxic strains examined fell into two distinct taxonomic groups. The first (IS5, EG2, IND, and W14 itself) lies within the previously recognized *P. luminescens* subsp. *akhurstii* subspecies. The second (Hb1 and Hm1) represents a different subgroup, *P. luminescens* subsp. *luminescens* (Fig. 9). The microarray analysis also revealed groups of genes either conserved or variable between the strains examined (Fig. 10). Conserved genes included genes such as *lux*, which produces light, a phenotype common to all *Photorhabdus* (Forst and Neilson, 1996). A series of putative virulence factors also appear conserved in most, or all, strains, including the toxin encoding gene *mcf1* (Daborn et al., 2002), *rtxA1* and *rtxA2*-like genes, the operon encoding the *prtA* protease, and an attachment and invasion locus (*ail*) homolog (ffrench-Constant et al., 2003). The type III secretion system (Waterfield et al., 2002), often associated with virulence in other Gram-negative bacteria (Galan and Collmer, 1999), is also present in all strains. Other conserved genes include those encoding catalase, chitinase, ferrochetalase, and flagellae. Variable genes include bacteriocins, toxins/hemolysins, insertion elements, pili, and genes involved in iron acquisition. Some toxin and hemolysin/hemagglutinin genes are also variable between strains. These include *pnf*, a *Photorhabdus* necrotizing factor that is found within a recently acquired region of the W14 genome (Waterfield et al., 2002) which is absent from TT01, and the *palA* and *palB* genes, encoding a hemolysin/hemagglutinin and its export activator (Waterfield et al., 2002). In W14, *palBA* is immediately downstream of the *mcf1* toxin gene and adjacent to a Phe tRNA (Waterfield et al., 2002) whereas in TT01 (Fig. 7), *palBA* is deleted from the equivalent location, as predicted. In contrast, a second two-component hemolysin locus *phlAB* (Brillard et al., 2002), is predicted to be similar in all strains, and indeed potentially duplicated in strain Hm.

The *tc* genes correspond to variable genes, whose distribution is strikingly split between orally toxic and nontoxic strains (Fig. 11). Orally toxic strains carry all three genes in the *tca* operon (*tcaA*, *tcaB*, and *tcaC*) whereas those lacking toxicity lack *tcaA* and *tcaB*. The genes of the *tca* operon are the only genes to show a perfect correlation with oral toxicity, and genes from *tcb*, *tcc*, and *tcd* are all variable across orally toxic strains. For the *tca* locus (Fig. 1), a comparison of W14 and TT01 shows two important findings. First, the W14 *tcaABC* operon is absent from the equivalent location in TT01. Second, a *tca*-like locus is present elsewhere in TT01 but lacks most of *tcaA* and *tcaB*, which have been deleted, and retains only a *tcaC1*-like gene. These observations confirm that the presence of *tcaAB* is necessary for oral toxicity of the bacterial supernatant. Further, the fact that *tca*-like loci can be found at different locations in different genomes supports the concept that the *tca* locus is mobile, as suggested by the presence of either a transposase, in W14, or an integration protein, in TT01, adjacent to both *tca*-like loci (Fig. 1). For the *tcb* locus, the suggestion that *tcbA* is lacking from TT01 is again confirmed by analysis of the genomic sequence, as *tcbA* is deleted from the equivalent location in TT01 and a transposase left in its place. Again comparing W14 and TT01, the array suggests that the *tcc* locus should be completely conserved, as supported by an examination of the genomic sequence. Finally for *tcd*, the genomic sequence (Fig. 3) confirms that all the *tc* genes of the island are present in both W14 and TT01, including both *lysR*-like regulators. Further, the predicted loss of *tcdA4* in group 2 orally toxic strains is confirmed by an

Fig. 9 Phylogenetic analysis of orally and nonorally toxic strains used in the microarray analysis based on 16S DNA sequencing. Note that orally toxic strains (*) fall into two well-supported phylogenetic groups. Strain TT01 (†) has recently been completely sequenced (see text).

examination of this locus in the Hb strain. The array even predicts the loss of *pdl1* and *pdl2* from within the *tcd* island of TT01, again confirmed by the sequence (Fig. 3). The localized deletion of *tcdA4*, and the apparent rearrangements mediated by *tccC*-like genes, again support the hypothesis that the *tcd* genes are encompassed in an unstable pathogenicity island. However, the consistent maintenance of four genetic elements within this island (*tcdA2*, *tcdB2*, a *gp13*-like holin, and the conserved region of *tccC3*), and the conserved organization of similar *tcd*-like genes in other bacteria (such as *sepA*, *sepB*, *orf4*, and *sepC* in *Serratia*), suggest that these genes form an invariant, but not orally toxic, core.

Previous analysis of strain W14 showed that either *tca* or *tcd* can independently contribute to oral toxicity. Thus plasmid clones of either *tca* or *tcd* from W14 confer recombinant oral toxicity when expressed in other nonorally toxic *Photorhabdus* strains, such as K122. This data is consistent with the current observation that the presence or absence of *tcaAB* is perfectly correlated with toxicity of the supernatant. However, all the *tc* genes within the *tcd* island are also present in some strains, such as TT01 (Fig. 3), which lack orally toxic supernatants. To investigate the apparent lack of oral toxicity associated with *tcd* in TT01, the toxicity of the bacterial cells was examined independently of their supernatant and it was found that toxicity is associated with the cells rather than the supernatant (Fig. 12). Confirmation that this novel cell-associated toxicity is *tcd* related now requires knockout or heterologous expression of this locus. In conclusion, even a very limited microarray can provide a powerful and predictive tool for correlating

Fig. 10 Diagrammatic representation of microarray results where DNA from orally and nonorally toxic strains was hybridized to 96 W14 virulence factor genes. Genes have been divided into conserved (showing a consistent hybridization signal in all strains) and variable (those showing a variable signal between strains). Note, for example, that the type III secretion system appears present in all *Photorhabdus* strains, whereas members of the *tcc* genes are variable (see text). The two loci implicated in oral toxicity are indicated: *tcaAB* (*) and *tcdAB* (†).

observed phenotypes with bacterial genotypes. Similar microarrays may therefore be useful in investigating other *Photorhabdus* phenotypes involved either in insect pathogenicity or symbiosis with their nematode hosts.

Conclusions

With the publication of the full genome sequence of strain TT01 and the ongoing sequencing of a *P. asymbiotica* strain at the Sanger Center, we are entering an era of comparative *Photorhabdus* genomics. As this article has indicated this now allows us to begin to determine where given toxin genes might have come from, and how they are passed between different strains. In the case of the *tcc* genes, the appearance of orally toxic *tca* genes in divergent strains and the finding that these genes can occur at different locations in the genome support the hypothesis that they are mobile between strains. Microarray analysis of more toxin genes in a wider array of strains may also cast light on the origins of other toxin genes such as *mcf1* and *mcf2*. Despite this recent explosion in sequence data, perhaps the most important biological questions remain largely unanswered. Thus, what is the biological role of the array of toxins

Fig. 11 Detailed analysis of the array results for *tc* genes only. In this diagram ratios close to 1 predict the presence of a gene and ratios greater than 0.5 (shaded histograms) predict it to be absent. Note that only the presence of *tcaAB* (*) is perfectly correlated with the presence of oral toxicity in the different strains (see text) and that *tcd* (†) is variable between strains.

that *Photorhabdus* encodes? Although it is easy to infer that these toxins may be necessary to kill the insect host, assessing the role of individual toxins via genetic knockout may be hampered by their functional redundancy. Thus, *tc* gene knockouts may show no oral activity but they can still kill the insect host. Further, mutants lacking *mcf1* take a longer time to kill insects but are still lethal. The current challenge is therefore to dissect out the individual roles of each toxin gene, even when they are members of large and rapidly growing gene families.

Fig. 12 Comparison of supernatant (SN) versus cell-associated oral toxicity for three different *Photorhabdus* strains. Note that strain TT01 containing a complete copy of the *tcd* locus has no oral toxicity associated with the bacterial supernatant but does show oral toxicity associated with the bacterial cells (see text for discussion).

Glossary

Archaea A phylogenetic domain of prokaryotes consisting of methanogens, halophiles, hyperthermophiles, and extreme acidophiles.

Autotroph An organism capable of using carbon dioxide (CO₂) as a sole source of carbon.

Carbonic anhydrase An enzyme involved in the transport and release of CO₂ from bicarbonate in physiological processes.

Carboxysomes Polyhedral microcompartments (PHMCs) (simple organelles) found in many autotrophic prokaryotes and capable of fixing CO₂ using the enzyme ribulose biphosphate carboxylase.

Chlorosomes The cigar-shaped organelles of green bacteria enclosed in a nonunit membrane containing the light-harvesting bacteriochlorophylls.

Gas vesicle A proteinaceous, gas-filled, cylindrical or conical inclusion (compartment) found in many prokaryotes. When present in sufficient numbers confers buoyancy to the cell.

Ladderanes Cyclobutane-containing lipids of planctomycetes.

Operon A prokaryotic transcriptional unit consisting of several different genes cotranscribed from one promoter.

Organelle (prokaryotic) A simple, but metabolically functional structure in prokaryotes that is surrounded by a barrier of some sort (protein shell or coat, a lipid monolayer, lipid-protein monolayer, or a unit membrane).

Planctomycetes Unusual members of Bacteria that lack peptidoglycan and contain membrane enclosed compartments inside the cell.

Proteasomes Large, nanocompartmentalized proteolytic machines that couple ATP hydrolysis with the unfolding and hydrolysis of protein substrates in the maintenance of protein quality and regulation of cell function.

Abbreviations

4HB	4-Hydroxybutyrate
ADRP	Adipose differentiation-related protein
atf	Acyltransferase
BChl	Bacteriochlorophyll
CDF	Cation diffusion facilitators
CGP	Cyanophycin grana protein
CP	Core particle
Csm	Chlorosome membrane
DAPI	4'-6'-Diamino-2-phenylindole
eGFP	Enhanced green fluorescent protein

FMO	Fenna–Matthews–Olson
HCR	High CO ₂ -requiring
L _{CM}	Core-membrane linker
MAI	Magnetosome island
Mam	Magnetosome membrane
MM	Magnetosome membrane
Mms	Magnetic particle membrane-specific
MTB	Magnetotactic bacteria
Mtx	Magnetotaxis
Ntn	N-terminal nucleophile
PBP	phycobiliprotein(s)
PBS	phycobilisome(s)
<i>Pdu</i>	Propanediol utilization
PHA	Polyhydroxyalkanoates
PHB	Poly(3-hydroxybutyrate)
PHMCs	Polyhedral microcompartments
PPKs	Poly P kinases
PPXs	Exopolyphosphatases
PS	Photosystem(s)
RuBisCo	Ribulose-1,5-bisphosphate carboxylase/oxygenase
SLD	Small lipid droplets
TAG	Triacylglycerol
WE	Wax esters

Defining Statement

Intracellular prokaryote inclusions, compartments and assemblages represent certain aspects of an organism's metabolic capability. Each of the structures, based on their primary function, is placed into one of three categories: (1) structures as metabolic machinery, (2) structures as contributors to cell mobility, (3) structures as metabolic reserves.

Introduction

The first observation of a prokaryote intracellular structure, a 'spherical body,' was in a 'colorless egg-shaped alga' in 1786, but the inclusion was not shown to be sulfur until nearly 100 years later. Other intracellular structures, gas vacuoles, and granules of cyanophycin, glycogen, lipid, and polyphosphate were observed toward the end of the nineteenth century, but were not extensively characterized until well into the twentieth century. Their clear-cut demonstration, isolation, and characterization awaited the availability of electron microscopy and the introduction of numerous techniques from a variety of disciplines including biochemistry, cell biology, genetics, microbiology, and molecular biology. The development of more sophisticated methodologies and technologies also gave rise to the discovery and characterization of many new structures. Discoveries and characterizations continue to this century.

The term 'inclusions' has been used for many years to categorize a wide variety of intracellular structures in prokaryotes. Although the term still appears to be applicable to some of the intracellular structures, the detailed examination and characterization elucidating the complexity of many of the structures, including some referred to as inclusions, has necessitated the introduction of new, more descriptive terms, for example, protein complexes, nano- and microcompartments, and simple organelles. In this article, a brief, up-to-date overview of each of the 14 intracellular structural types is given. Each of the structures, based on their primary function, is placed into one of three categories: (1) structures as metabolic machinery, (2) structures as contributors to cell mobility, and (3) structures as metabolic reserves. For more details on the structures as well as information on less common or less studied structures the reader is directed to 'Further reading.'

Structures as Metabolic Machinery

Carboxysomes and Other Polyhedral Microcompartments

Polyhedral microcompartments (PHMCs) are regularly shaped proteinaceous complexes 90 to over a few hundred nm in diameter that consist of a thin (3–4 nm) protein shell and a core of metabolically active enzymes. They are believed to be functionally analogous to eukaryotic organelles and have been classified into at least seven different types, depending on the enzymes they

sequester, but their exact role in various aspects of microbial metabolism in which they are thought to participate have not yet been fully elucidated. On the basis of comparative genomic analysis, PHMCs are predicted to exist in a wide range of bacterial lineages. Apart from their distinct polyhedral appearance and despite their diverse proposed metabolic roles, all PHMCs share two families of genes that are required for the formation of their shells. One of these (Pfam 00936) encodes the major shell proteins, which assemble into hexamers that form the facets of the polyhedral PHMC shell. The proteins encoded by the other family (Pfam 03319) are minor shell components that are thought to occupy the vertices of the polyhedra. The similar amino acid sequences of the shell proteins belonging to these families in different PHMCs suggest a common role in metabolic organization that serves to optimize and perhaps regulate metabolic flow through the particles by an as yet poorly understood molecular mechanism.

The PHMCs that were identified first were the carboxysomes. These organelles were originally detected by electron microscopy as 'polyhedral bodies' in thin sections of cyanobacteria and have since been shown to be present in all cyanobacteria and in many chemoautotrophs (Figure 1(a)–1(c)). Biochemical analysis of purified carboxysomes from the chemoautotrophic sulfur oxidizer *Halothiobacillus neapolitanus* demonstrated that their lumen is filled with the CO₂-fixing enzyme ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBisCO), the key enzyme of autotrophic carbon metabolism (Figure 1(d)). This discovery led to the term carboxysomes for the microcompartments of autotrophic bacteria. Pure *H. neapolitanus* carboxysomes were subsequently dissected molecularly into multiple polypeptides, which are present in the microcompartment in defined stoichiometric relationships. Partial sequence determination of individual carboxysome proteins led to the identification of their genes. The manner in which most of the carboxysome genes are arranged in the genome of *H. neapolitanus* and in many other autotrophs suggests that they form an operon consisting of *cbbL* and *cbbS*, the genes for the large and small subunit, respectively, of RuBisCO; *csoS2*, a gene that specifies a shell protein of unknown function; *csoS3*, which encodes the carboxysomal carbonic anhydrase; and *csoS1A*, -B, and -C, three paralogs that code for the Pfam 00936 shell proteins. The *csoS4A* and -B genes encode the Pfam 03319 vertex proteins.

Mutants of cyanobacteria and chemoautotrophs that lack carboxysomes display a high CO₂-requiring (HCR) phenotype and either grow poorly or not at all at ambient CO₂ concentrations. On the basis of these observations, a model has been proposed in which carboxysomes function as the final component of a carbon dioxide (CO₂)-concentrating mechanism that improves the CO₂ fixation ability of the sequestered RuBisCO. Most autotrophic bacteria concentrate inorganic carbon as cytosolic bicarbonate to levels as much as 1000 times higher than those in their extracellular environment. Since RuBisCO is only able to utilize CO₂ as a

(2001) Microcompartments in prokaryotes: Carboxysomes and related polyhedra. *Applied Environmental Microbiology* 67: 5351–5361.

substrate, the carboxysomal carbonic anhydrase is required to rapidly convert HCO_3^- to CO_2 , thereby effectively raising its local concentration in the vicinity of the sequestered RuBisCO. The structure of the major shell proteins suggests that the shell may actively regulate access of small molecules to the carboxysome interior and may thereby limit the competitive inhibition of RuBisCO activity by oxygen.

PHMCs in heterotrophic bacteria have been referred to as enterosomes, polyhedral organelles, or metabolosomes. The particles from propanediol-grown *Salmonella enterica* (Figures 1(e)–1(g)) contain multiple enzymes that participate in propanediol degradation; their shells are formed by orthologs of the two common PHMC shell proteins. The proteins are encoded by the 23 genes of the propanediol utilization (*pdu*) operon. The organelle may prevent release of the toxic intermediate propionaldehyde into the cytoplasm. Similar particles that are formed by *S. enterica* grown on ethanolamine contain ethanolamine ammonia lyase and are believed to prevent the escape of acetaldehyde, a volatile intermediate of the ethanolamine degradation pathway.

Judging from the data emerging from the ever-growing list of sequenced bacterial genomes, homologues of genes that encode PHMC shells are widespread among the bacteria, and it appears that organization of key enzymes by carboxysome-like shell proteins is a general mechanism used by bacteria to enhance or control crucial metabolic steps. In recent years, the potential of PHMCs for synthetic biology purposes has led to multiple interdisciplinary research efforts that have tackled the molecular mechanism of enzyme sequestration and PHMC assembly, the physical characteristics of the shell, and the molecular mechanism behind PHMC function.

Anammoxosomes

Anammoxosomes are unique metabolically significant compartments performing the **anammox** process found so far only within anaerobic planctomycetes. These bacteria carry out **Anaerobic Ammonium Oxidation**, a chemolithotrophic and usually autotrophic metabolism of significant environmental importance. They comprise *Candidatus* genera 'Brocadia,' 'Kuenenia,' 'Scalindua,' all autotrophs, and 'Anammoxoglobus,' which exhibits some heterotrophic oxidation of propionate as well as autotrophic ammonium oxidation. These have been mostly characterized from wastewater treatment bioreactors and none are yet in pure culture. Representatives also occur widely in marine sediment and other marine anaerobic habitats. During anammox metabolism, ammonium is oxidized under anaerobic conditions using nitrite as the electron acceptor with molecular dinitrogen as the final product. The anammox process is of major significance for the global nitrogen cycle, especially from their activity in anoxic marine water and sediment. Carbon dioxide is fixed when anammox organisms grow anaerobically on ammonium and some nitrite is oxidized anaerobically to nitrate and this may supply electrons for carbon dioxide reduction via reverse electron transport. Anammox planctomycetes thus need only ammonium, nitrite and carbon dioxide as major growth substrates. In recent models the mechanism is thought to involve nitric oxide generated from nitrite reduction which oxidizes ammonium to yield hydrazine which is in turn oxidized to dinitrogen. Like the cells of other planctomycetes, all named anammox species possess a planctomycete-characteristic cell plan involving a single-membrane-bounded pirellulosome compartment containing the nucleoid as well as a paryphoplasm region surrounding the outer rim of the cell. Within the pirellulosome however they possess another single-membrane-bounded compartment, the anammoxosome, unique to anammox planctomycetes (Figure 2(a)). The anammoxosome envelope divides the cell cytoplasm into two compartments, the riboplasm outside the anammoxosome and the contents of the anammoxosome. The anammoxosome harbours at least one specialized enzyme, a hydrazine oxidoreductase functional in the mechanism of anaerobic ammonium oxidation and important to formulation of models for anammox metabolism.

The anammoxosome is wrapped in a single-membrane envelope possessing unique cyclobutane-containing lipids termed ladderanes (Figure 3), which may confer relatively high density and impermeability to the anammoxosome membrane. Intriguingly from an evolutionary perspective, the ladderanes occur in both ether-linked and ester-linked forms in these mesophiles. This envelope has been hypothesized to have specialized functional roles e.g. providing protection from toxic intermediates of anammox metabolism (such as hydrazine) and responsibility for vectorial proton gradient formation related to bioenergetic mechanisms of anammox metabolism.

The anammoxosome and its envelope have formed an important part of models of anaerobic ammonium oxidation in these bacteria. According to these models (Figure 4), during electron transport occurring along with ammonium oxidation, protons are consumed in the riboplasm and protons generated inside the anammoxosome, so that a proton gradient is generated relative to an alkaline riboplasm. An ATPase/synthase embedded in the anammoxosome envelope would then be responsible for ATP synthesis chemiosmotically from the proton gradient generated by electron transport during ammonium oxidation. Such an ATPase/synthase is detectable via immunogold electron microscopy associated with anammoxosome membrane, and a pH gradient detected via NMR, consistent with this model. The anammoxosome membrane also may be the site of cytochrome c maturation. The anammoxosome has other characteristics which may relate more to cell biology, since within the anammoxosome tubules have been demonstrated which in some cases form distinct arrangements suggesting a cytoskeletal function (Figure 2(b)), and nucleoid is often in contact with anammoxosome envelope. The anammoxosome has the potential to be the first planctomycete compartment for which a specialized functional role will be demonstrated. This may occur with help of data from the '*Candidatus Kuenenia stuttgartiensis*' genome project, which is among the first such projects to sequence the complete genome of a bacterium not yet available in pure culture. A near-complete 4.2 Mb genome sequence for *Candidatus Kuenenia stuttgartiensis* is available and has yielded insights about models for metabolism catalyzed by the anammoxosome and how ladderane lipids may be synthesized.

Figure 2 (a) Transmission electron micrograph of thin section of cryosubstituted cell of *Candidatus Brocadia anammoxidans*, from a bioreactor performing anaerobic ammonium oxidation. A central anammoxosome (A) is surrounded by a single membrane (AM). The cytoplasm external to the AM contains the nucleoid (N) and ribosome-like particles and is surrounded by the intracytoplasmic membrane (ICM) defining the pirellulosome. A paryphoplasm (P) lies at the rim of the cell between the ICM and the cytoplasmic membrane closely apposed to the cell wall. Tubule structures are visible inside the anammoxosome. Bar = 0.1 μm . (b) Transmission electron micrograph of thin section of cryosubstituted cell of *Candidatus Brocadia anammoxidans*, from a bioreactor performing anaerobic ammonium oxidation. An apparently dividing cell in which the central anammoxosome contains tubules, some of which are seen in longitudinal section oriented perpendicular to the plane of division; a nucleoid is seen in each half of the dividing cell accompanying the corresponding anammoxosome half section. Bar = 200 nm. Courtesy of J. A. Fuerst, R. Webb and M. Strous. Chlorosomes

Chlorosomes are light-harvesting organelles that are tightly appressed to the inner surface of the cytoplasmic membranes of green chlorophototrophic bacteria (Figure 5(a)). Green bacteria are a loose assemblage of organisms belonging to three bacterial phyla: *Chlorobi*, *Chloroflexi*, and *Acidobacteria*. Green bacteria share two defining properties: they synthesize either bacteriochlorophyll (BChl) *c*, *d*, or *e*, and they assemble these BChls into chlorosomes. Chlorosomes can accurately be described as 'sacs containing supramolecular aggregates of BChl *c*, *d*, or *e*' (Figure 5(b)). The aggregates formed from BChl *c* and *d* in chlorosomes cause a red-shift of 70–80 nm in the Q_y absorption, which allows cells to absorb near-infrared light at ~730–750 nm that is not absorbed by other Chls, especially Chl *a*. Aggregates formed from BChl *e* gain an absorption band at ~525 nm that allows organisms producing this pigment to harvest blue light very efficiently, and thus these organisms can grow at great depths in aquatic environments. The light energy absorbed by BChls in chlorosomes is rapidly and efficiently transferred to homodimeric type-1 photochemical reaction centers in the cytoplasmic membranes via BChl *a* molecules associated with chlorosome baseplate protein, CsmA (Figure 5(c)), and the BChl *a*-binding Fenna–Matthews–Olson (FMO) protein in chlorosome-producing members of the *Chlorobi* and *Acidobacteria* (Figure 5(c)). In chlorosome-producing members of the *Chloroflexi*, a membrane-associated BChl *a*-binding light-harvesting complex (B808–866) replaces FMO. Similar to light-harvesting complex I (LH-I) in purple bacteria, this complex forms a ring that surrounds the type-2 photochemical reaction centers found in chlorophototrophic members of the *Chloroflexi*.

Chlorosomes of the green sulfur bacterium *Chlorobaculum tepidum* (phylum *Chlorobi*) have been most extensively characterized. A single *Cba. tepidum* chlorosome can contain up to 250 000 BChl *c* molecules, and because a cell can have up to ~200 chlorosomes,

Note that in one alternative, nitric oxide can substitute for the place of hydroxylamine in the model shown here. Reproduced from van Niftrik LA, Fuerst JA, Sinninghe Damsté JS, et al. (2004) The anammoxosome: An intracytoplasmic compartment in anammox bacteria. *FEMS Microbiology Letters* 233: 7–13, with permission from FEMS Microbiology Letters (Elsevier).

a *Cba. tepidum* cell may contain ~50 million BChl *c* molecules (i.e., BChl *c* comprises ~30% of the cell carbon). In addition to BChl *c*, *Cba. tepidum* chlorosomes contain about 2500 BChl *a* molecules, 5000 protein molecules (all are found in the envelope, about half of which are the small BChl *a*-binding baseplate protein, CsmA), 20 000 carotenoids, 18 000 chlorobiumquinone and menaquinone molecules, and 20 000 lipid molecules (glycolipids, phospholipids, and wax esters). Chlorosomes are surrounded by a protein-stabilized, glycolipid ‘monolayer’ envelope that is ~3 nm thick. This envelope is an asymmetric bilayer membrane, in which proteins and glycolipids form the outer leaflet, and the tails of the BChl molecules inside form the inner leaflet (Figure 5(c)). The envelope of *Cba. tepidum* chlorosomes contains ten proteins belonging to four structure motif families: 1, CsmA/CsmE; 2, CsmB/CsmF/CsmH; 3, CsmC/CsmD/CsmH; and 4, CsmI/CsmJ/CsmX. Mutants lacking individual proteins except CsmA or up to four different proteins have been constructed. CsmA (and probably CsmE) forms dimers which in turn are organized into a paracrystalline baseplate structure that attaches the chlorosome to underlying FMO complexes (Figure 5(c)). Each CsmA polypeptide binds a single BChl *a* molecule and 1 or 2 carotenoid molecules as well. The proteins of motif families 2 and 3 help to determine the shape of the chlorosome and possibly influence the organization of the BChl aggregates inside. CsmI/CsmJ/CsmX bind [2Fe-2S] clusters; these proteins transfer electrons to reduce a quenching species, thought to be oxidized quinones, to reactivate energy transfer after cells or chlorosomes have been exposed to oxygen (see Figure 5(c)).

Figure 5 Structures of chlorosomes from the green sulfur bacterium *Cba. tepidum* and *Cab. thermophilum*. (f) Electron micrograph of a single, negatively stained chlorosome from the *bchQ bchR bchU* mutant of *Cba. tepidum*. (g) Cryo-electron micrograph showing the structure of [8-Et, 12-Me]-Bchl *d* molecules in chlorosomes of a *bchQ bchR bchU* mutant of *Cba. tepidum*. The 2.1-nm lamellar spacings between BChl *d* surfaces are indicated by three horizontal white arrows, and the 0.83-nm spaces between the *syn-anti* BChls of the dimer stacks are indicated by four vertical white arrows. (h) Cryo-electron micrograph showing an end view of a single chlorosome from the *bchQ bchR bchU* mutant of *Cba. tepidum*. The three vertical white arrows indicate the lamellar surfaces that are formed from the *syn-anti* monomer stacks of [8-Et, 12-Me]-Bchl *d* and that are separated 2.1 nm. (i–j) Schematic drawings showing the organization of the *syn-anti* dimer stacks of [8-Et, 12-Me]-Bchl *d* in the chlorosomes of the *bchQ bchR bchU* mutant of *Cba. tepidum* (i) and of BChl *c* molecules in wild-type chlorosomes (j). BChls in *syn* configuration are shown in orange and BChls in *anti* configuration are shown in aqua. (k) Schematic drawing showing the overall organization of [8-Et, 12-Me]-Bchl *c* molecules in a *bchQ bchR* mutant of *Cba. tepidum*. The BChls form parallel monomer stacks of all-*syn* and all-*anti* configuration, which can adopt different suprastructures as shown.

The length and diameter of chlorosomes are highly variable and may vary considerably as a function of organism, light intensity, and growth conditions (Figure 5(b), 5(d) and 5(f)). This variability arises from the mechanism of chlorosome assembly, but is probably regulated in response to light and other parameters as well. Cryo-electron microscopy of chlorosomes from wild-type *Cba. tepidum* showed that the internal organization of the BChls in each chlorosome is unique: i.e., no two chlorosomes are structurally alike. Because of the heterogeneity in size, composition and internal structure, structural studies on chlorosomes were quite challenging, and they were the last class of light-harvesting complexes to be characterized in this way. End-on views of chlorosomes revealed that the BChl *c* molecules form coaxial, concentric nanotubular suprastructures with arched, interconnecting lamellae. The surface layers formed by the tetrapyrrole head groups of the BChls are separated by about 2.1 nm (Figure 5(g) and 5(h)), which are established by the hydrophobic interactions of the farnesol tails of the BChls in two adjacent layers, in a manner similar to the way that hydrophobic interactions of fatty acids occur in a lipid bilayer membrane. Solid-state NMR studies established that the BChls in chlorosomes of a mutant producing only [8-Et, 12-Me]-Bchl *d* (Figure 5(i)) as well as in wild-type *C. tepidum* (Figure 5(j)), form *syn-anti* monomer stacks arranged in shallow helices. The farnesol tail of one BChl *c* molecule extends above, and of the other below, the

plane formed by the head groups. In a mutant that produces mostly [8-Et, 12-Me]-BChl *c*, the BChls form adjacent all-*syn* and all-*anti* parallel monomer stacks (Figure 5(k)). In all cases, hydrophobic interactions produced by the tails and the BChls and ligation of adjacent BChls by the C-3¹ hydroxyl group are key features that drive the self-aggregation of the BChls.

The chlorosomes of *Cfx. aurantiacus* (120 × 44 × 30 nm; 84 000 nm³) and *Cab. thermophilum* (99 × 40 × 31 nm; 65 000 nm³) are significantly smaller than those of *Cba. tepidum* (133 × 57 × 36 nm; 141 000 nm³), and correspondingly must contain fewer BChl *c* molecules. The baseplate of *Cfx. aurantiacus* chlorosomes also forms a distinctive paracrystalline lattice with a 3.3-nm spacing, which is probably also formed from CsmA dimers. With the exception of CsmA, the proteins of the chlorosome envelope in *Cfx. aurantiacus* exhibit very limited sequence similarity to those of *Cba. tepidum*, but proteins of the same four motif families appear to be present. Chlorosomes of *Cab. thermophilum* differ structurally from those of *Cba. tepidum* and *Cfx. aurantiacus* (Figure 5(d)). Cryo-electron microscopy has demonstrated that the BChl *c* suprastructure of these chlorosomes has a lamellar spacing of ~2.3 nm (Figure 5(e)), a little larger than other chlorosomes; however, the BChl *c* molecules clearly do not form concentric nanotubes. Instead, the BChls seem to form twisted, sheet-like structures, which in turn form irregular subdomains within the chlorosomes. Two envelope proteins in *Cab. thermophilum*, CsmA and a protein with a [2Fe-2S] binding domain, share sequence similarity to chlorosome envelope proteins of *Cba. tepidum* and *Cfx. aurantiacus*. However, the other five proteins exhibit no sequence similarity with chlorosome envelope proteins in members of the *Chlorobi* or *Chloroflexi*. The structural similarity of chlorosomes in three of distantly related taxa that synthesize BChls, two of which have homodimeric type-1 reaction centers, suggests that chlorosomes are an ancient invention of nature, which may have evolved shortly after the evolution of type-1 reaction centers.

Phycobilisomes

Phycobilisomes (PBS) are very large (5–30 MDa) antenna protein complexes that occur in most cyanobacteria and the chloroplasts of red algae. PBS are composed of water-soluble phycobiliproteins (PBP) and 'linker' proteins, which commonly lack chromophores and direct the assembly of PBP into PBS. PBP complexes absorb visible light wavelengths for use in photosynthesis that are not efficiently absorbed by chlorophyll *a*. PBS are mostly associated with Photosystem (PS) II, which has only 35 chlorophyll *a* molecules per monomer (PS I has 96 chlorophyll *a* molecules per monomer), but PBP also transfer energy to PS I under some light conditions. Because these PBP complexes can absorb most of the visible spectrum, they are highly beneficial to organisms by increasing both their total absorbance capacity as well as enabling the use of additional, specific wavelengths of light that can be used for photosynthesis.

PBS are tightly associated with the cytoplasmic surface of the thylakoid membrane and project into the stromal region. When viewed by electron microscopy of thin sections of cells, they often form densely packed, interdigitating rows on the surfaces of adjacent thylakoids (Figure 6(a)–6(c)). Five structural classes of PBP antenna structures have been described, which vary in size, shape, and compositional complexity. These include: (1) hemi-ellipsoidal PBS; (2) hemi-discoidal PBS; (3) bundle-shaped PBS; (4) block-shaped PBS; and (5) rod-shaped PBS. Hemi-ellipsoidal and block-shaped PBS, which are mostly found in red algal chloroplasts, are the largest known PBS and can have sizes up to ~30 MDa. Most cyanobacterial PBS are smaller, hemidiscoidal structures with masses of 4.5–15 MDa (45–70 (w) × 30–50 (h) × 17 nm (d)). Hemi-discoidal PBS can add 300–800 chromophores to the absorption cross-section of PS II, which helps to balance the electron throughput between PS II and PS I. *Gloeobacter violaceus*, the only cyanobacterium that lacks thylakoid membranes, has large, bundle-shaped PBS that form a cortical layer by standing perpendicular to the inner surface of the cytoplasmic membrane. These PBS are formed from a hexagonally packed bundle of six PBP rods that are 50–70 nm in length with a diameter of 10–12 nm (i.e., the diameter of a trimeric (α₃β₃) PBP disc). Finally, simple, rod-shaped PBP aggregates have been shown to occur in some cyanobacteria. These seem to be composed of one PBP (phycocyanin) or sometimes two PBP, and they include a specialized, rod-membrane linker protein (CpcG2 of *Synechocystis* sp. PCC 6803 or CpcG3 of *Nostoc* sp. PCC 7120) that has a hydrophobic, α-helical domain that anchors the rod complex to PS I. A long-standing mystery surrounding PBS is that they dissociate into their constituent PBPs and linker proteins when cells are disrupted in aqueous buffer at low ionic strength. The isolation of intact PBS requires the use of cross-linking agents and/or high-molarity phosphate buffer (0.5–0.75 M phosphate at near-neutral pH). Release of PBS from the thylakoid membrane usually requires the complete dissolution of the thylakoid membrane using detergents.

PBP are a superfamily of brilliantly colored, water-soluble proteins that are derived from an ancestral protein by gene duplication and divergence. Crystallography has shown that the major PBP phycoerythrin (red-colored, green-absorbing), phycoerythrocyanin (fuchsia-colored, yellow-absorbing), phycocyanin (blue-colored, orange-absorbing) and allophycocyanin (aqua-colored, red-absorbing) proteins all form torroid-shaped (α₃β₃) trimers comprised of (αβ) protomers or face-to-face (αβ)₆ hexamers. The α and β subunits of allophycocyanin each carry one phycocyanobilin chromophore, which is covalently attached to residue cysteine 82 by a single thioether linkage. The α and β subunits of phycocyanin carry one and two phycocyanobilin chromophores, respectively. The alpha subunit chromophore is attached to cysteine 84, and the β subunit chromophores are attached to cysteines 82 and 153. Phycoerythrin subunits carry two (α) and three (β) three phycoerythrobilin chromophores. Three bilin lyases are sufficient to attach phycocyanobilin to allophycocyanin and phycocyanin subunits except ApcE. The CpcE/CpcF bilin lyase attaches phycocyanobilin to cysteine 84 of the apo-α subunit of phycocyanin; CpcT attaches phycocyanobilin to the cysteine 153 of the β subunit; and a homodimer (CpcS₂) or a heterodimer (CpcS/CpcU) attaches phycocyanobilin to cysteine 82 of all other PBP. ApcE, which is the core-membrane linker of the PBS core, is the only PBP that auto-ligates phycocyanobilin to cysteine 186 in its biliprotein domain. Two additional chromophores, phycoviolobilin (α subunit of phycoerythrocyanin) and phycourobilin (some phycoerythrins), can be introduced into some cyanobacterial PBP by isomerization reactions that occur during chromophore attachment by so-called isomerizing lyases.

Figure 6 Phycobilisomes. (a) Electron micrograph of a thin section of the cyanobacterium *Pseudanabaena* sp. PCC 7409. The three arrows point to rows of PBS. (b) Enlarged view of the boxed region of panel (a), which shows a cross-section of the interdigitating rows of PBS on the stromal surfaces of the paired thylakoid membranes. (c) Longitudinal section of rows of PBS which are standing perpendicular to the thylakoid membranes. (d) Diagram showing the structural organization of the hemidiscoidal PBS of the cyanobacterium *Synechococcus* sp. PCC 7002. The tricylindrical core is mostly comprised of allophycocyanin (aqua; ApcA and ApcB); the six peripheral rods are each composed of two phycocyanin ($\alpha\beta$)₆ hexamers (blue; CpcA and CpcB), which are assembled by linker proteins CpcC, CpcD, and CpcG. Ferredoxin:NADP⁺ oxidoreductase (PetH; yellow) has a CpcD domain and occurs at ~2 copies per PBS. (e) Compositional details of the subcomplexes of a tricylindrical PBS core. The complexes of the two lower cylinders have an anti-parallel configuration. (f–h) Examples of other peripheral rod complexes. The complexes shown in (f) and (g) occur in PBS of *Pseudanabaena* sp. PCC 7409 when cells are grown in green or red light, respectively. (f) Peripheral rod composed of one phycocyanin hexamer (blue) and two phycoerythrin hexamers (red). (g) Peripheral rod composed of one hexamer of phycocyanin-1 and two hexamers of phycocyanin-2. (h) Peripheral rod composed of two hexamers of phycocyanin (blue) and a hexamer of phycoerythrocyanin (violet).

The PBS of the cyanobacterium *Synechococcus* sp. PCC 7002, which forms simple hemidiscoidal structures from twelve gene products, are principally comprised of peripheral rods composed of phycocyanin and a tricylindrical core substructure composed of allophycocyanin (Figure 6(d)). Each of six peripheral rods is formed from two phycocyanin ($\alpha\beta$)₆ hexamers (CpcA = α ; CpcB = β), and three linker proteins: CpcD, the rod-terminating linker; CpcC, the peripheral rod linker; and CpcG, the rod-core linker. In PBS, CpcD is sometimes replaced by PetH, ferredoxin:NADP⁺ oxidoreductase, which also has an N-terminal CpcD domain. This presumably places PetH in close proximity to PS I and limits the diffusion distance required for ferredoxin to deliver electrons to NADP⁺. The core substructure is composed of six proteins: ApcA, ApcB, ApcC, ApcD, ApcE and ApcF. ApcE is the core-membrane linker (L_{CM}), which acts as a scaffold for assembly of the core substructure. In PBS with bicylindrical cores (e.g., *Synechococcus* sp. 7942), this ~75-kDa protein has an N-terminal PBP domain that binds one phycocyanobilin and two REP (linker) domains, with intervening spacer sequences. This protein can direct the assembly of a core with two allophycocyanin cylinders. PBS with tricylindrical cores (e.g., *Synechococcus* sp. PCC 7002 (see Figure 6(e))) have larger, 99-kDa ApcE proteins with three REP domains, and PBS with pentacylindrical cores (e.g., *Nostoc* sp. PCC 7120) have 120-kDa ApcE proteins with 4 REP domains. Two ApcE polypeptides are required to produce one core, the remainder of which is mostly made up of ($\alpha\beta$)₃ trimers of allophycocyanin (ApcA, ApcB). ApcC is a small, cylinder-terminating core linker protein; ApcF is a beta-type subunit that is the assembly partner of the PBP domain of ApcE; and ApcD encodes an α -type subunit that is found in the outer most trimer of the bottom cylinders of the core (one copy for each cylinder on average). ApcE and ApcD are often referred to as 'terminal emitters,' because they are associated with the longest wavelength absorption (665 and 670 nm, respectively) and because they are responsible for the fluorescence emission of isolated PBS. ApcE is the primary pathway for energy transfer to PS II via PsbC *in vivo*, and ApcD is principally responsible for energy transfer to PS I via PsbA. The degree to which energy is directed to the two photosystems is controlled by a process known as 'state transitions,' which alters the coupling of PBS to PS II and/or PS I.

PBPs are arranged within the PBS in a downhill energy transfer cascade such that shorter-wavelength-absorbing proteins of higher energy occur at the periphery of the PBS and transfer energy to longer-wavelength absorbing species of lower energy in the

PBS core. This arrangement ensures rapid, efficient and largely unidirectional energy transfer to PS I and PS II complexes in the thylakoid membrane. Thus, when they occur in PBS, phycoerythrin or phycoerythrocyanin are located at the core-distal ends of the peripheral rods (see Figure 6(f)–6(h)). Such peripheral rods always contain some phycocyanin, which is located proximal to the core and which facilitates efficient energy transfer to allophycocyanin in the core. In turn, the core components and especially the terminal emitters promote efficient energy transfer to the chlorophylls associated with photosystems in the thylakoids. Some cyanobacteria can alter the composition of their PBS to match the incident light, a process known as complementary chromatic acclimation. A variation of this phenomenon occurs in some marine cyanobacteria, which respond to blue light by reversibly isomerizing the phycoerythrobilin chromophores to phycourobilin chromophores.

Proteasomes

Proteasomes are large, multicatalytic proteases that are widespread in archaea, eukaryotes and bacteria of the phylum Actinobacteria. Proteasomes are important in general protein turnover, the removal of damaged and foreign proteins as well as regulatory proteolysis. Protein modification pathways (i.e., ubiquitylation in eukaryotes, pupylation in mycobacteria and sampylation in archaea) that mediate the covalent attachment of ubiquitin or ubiquitin-like proteins to protein targets are regulated and often mark the tagged protein for destruction by proteasomes. Proteins specifically directed to proteasomes for proteolysis encompass a variety of functions, including those associated with cell division, metabolism, DNA repair, translation, transcription and pathogenesis, making proteasomes and their associated protein tagging mechanisms attractive targets for chemotherapy, pathogen control, and biotechnology applications.

Proteasomes have a nanocompartmentalized architecture that is characterized by the sequestration of proteolytic active sites on the interior of a chamber-like structure. This arrangement minimizes the uncontrolled hydrolysis of cellular components and promotes the proper selection, unfolding and translocation of substrate proteins for degradation by proteasomes through energy-dependent processes.
